SUBSECTION VII Paramyxoviridae

Parainfluenza Viruses

179

Robert C. Welliver Sr

The human parainfluenza viruses (hPIVs) are ubiquitous agents with well-earned recognition as being among the most important viral respiratory pathogens of humans. The three major hPIVs (1 to 3) have been estimated to be among the three most frequent causes of hospitalizations for young children with respiratory tract illnesses.^{91,92,101} The impact of these three hPIVs on health care resources is demonstrated by the 16,000 to 100,000 hospitalizations each year they are estimated to cause among children younger than 5 years.⁴⁸ Hospitalizations from hPIV-3 alone are estimated to range from about 9000 to 52,000 each year. The rates of outpatient visits for hPIV infections among young children are even higher, estimated to be 10 times the hospitalization rates.⁶² One study estimated that the cost of emergency visits and hospitalization from croup resulting from parainfluenza alone was \$20 to \$56 million.⁹² The costs imposed by the burden of all the hPIVs, types 1 to 4, and at all ages have not been estimated.

Respiratory tract illnesses from the hPIVs may occur and recur throughout life, and they are subordinate only to respiratory syncytial virus (RSV) in the morbidity caused by acute lower respiratory tract disease in infants and young children.²¹⁶ Among the causative agents of acute laryngotracheitis or “croup,” the hPIVs are second to none.¹⁷⁵ The epidemic nature of hPIV types 1 and 2, the prolonged seasonal occurrence of type 3, and the ability of all types to cause repeated infections throughout life indicate why they continue to be important despite the technological advances that have been made toward control of viral diseases.

HISTORY

The historical delineation of the parainfluenza viral family is intertwined with the discovery of the related animal viruses and marked by the colorful names descriptive of their origin (Table 179.1). The first strain of PIV was discovered in Japan and named *Sendai*, or the hemagglutinating virus of Japan (HJV).¹²⁰ This agent was recovered from mice that had been inoculated with postmortem lung tissue of infants with pneumonia (some confusion may have existed, as mouse Sendai virus essentially does not infect humans). The first PIV from human sources was recovered several years later by Chanock³⁶ from infants with croup, and thus it became known as the croup-associated (CA) virus. Subsequently, three additional hPIVs that were distinct antigenically were isolated from children with acute respiratory illness.^{38,105} In contrast to the CA virus, which was recognized by its ability to produce syncytia in tissue culture, the strains of the next two types of PIVs produced few or no cytopathic effects but were recognized by their ability to cause hemadsorption of guinea pig erythrocytes to infected tissue culture. These viruses thus were called hemadsorption type 1 (HA-1) and hemadsorption type 2 (HA-2) viruses.

Once the similarity of the familial characteristics of the CA virus to those of the other three viruses was recognized, the viruses were renamed the hPIVs, type 1 (HA-2), type 2 (CA), and type 3 (HA-1).⁶ The fourth hPIV, discovered subsequent to this reclassification, is without a sobriquet and simply is termed hPIV-4, with two subtypes, A and B. The first type 4 strain was recovered in monkey kidney cell culture from a college student afflicted with a common cold.¹⁰⁵

Several animal species appear to be natural hosts to the PIVs (see Table 179.1), with the exception of hPIV-4, which has been found only in humans. In animals, PIVs may be important pathogens. Bovine PIV (bPIV), similar to hPIV-3, often in combination with infection by *Pasteurella* organisms, causes an illness of considerable morbidity and cost in cattle termed *shipping fever*. Naturally acquired antibodies to the PIVs are found not only in cows but also in rodents, monkeys, rabbits, and other mammals. Various rodents, along with ferrets, dogs, and lambs, have been used for experimental infection.²⁰⁸ The virus previously named *equine Morbillivirus* has been demonstrated to be in the Paramyxoviridae family and named *Hendra virus*. This virus, which causes lethal illness in horses, was recognized to cause illness in humans also. Individuals in close contact with horses in Australia contracted the virus, and two died.¹⁶² Subsequently, in 1998, an outbreak of severe, often fatal encephalitis occurred in Malaysia and Singapore in individuals who had close contact with pigs.^{43,72} The agent of this outbreak, Nipah virus, is phenotypically and antigenically similar to Hendra virus (80% genomic homology).

CHARACTERIZATION OF PARAINFLUENZA VIRUSES

Classification and Structure

The five hPIVs, hPIV serotypes 1, 2, 3, 4A, and 4B, are members of the Paramyxoviridae family, belonging to the *Respirovirus* and *Rubulavirus* genera (Fig. 179.1). The Paramyxoviridae family also includes other human viral pathogens transmitted via the respiratory route, such as RSV, measles, mumps, and metapneumovirus. The PIVs are distinguishable from the orthomyxoviruses (i.e., influenza viruses) in their size, nucleocapsid structure, antigenic composition, and laboratory growth characteristics.

hPIVs are nonsegmented, single-stranded, negative-sense, enveloped RNA viruses appearing as pleomorphic particles of medium size, with an average diameter of 150 to 200 nm.^{111,195} The genomes of all the hPIVs, consisting of an average of approximately 15,000 nucleotides, code for at least six structural proteins (3'-N-P-M-F-HN-L-5') and one or more nonstructural proteins (C, V, D) (Fig. 179.2). The viral ribonucleoprotein (RNP) is the viral RNA, tightly encapsulated by the nucleoprotein (NP). It is surrounded by the envelope, derived from the

TABLE 179.1 Parainfluenza Viruses

Parainfluenza Virus Type/ Related Animal Virus	Natural Host	Experimental Infection	Preferred Tissue Culture for Initial Isolation	CYTOPATHIC EFFECT	
				Initial Isolation	Passage
Parainfluenza type 1, hemadsorption type 2 (HA-2)	Human, guinea pig, rabbit, monkey, marmoset	Hamster, ferret	Monkey kidney, human diploid, human embryonic kidney	±	Rounding, cell destruction
Sendai, hemagglutinating virus of Japan (HVJ)	Mouse, pig				
Parainfluenza type 2	Human, monkey, rabbit, guinea pig	Hamster, dog	Monkey kidney, human embryonic kidney	+ (syncytial on monkey and human cells)	Syncytial, "Swiss cheese"
Simian virus 5 (SV 5)	Monkey				
Simian virus 41 (SV 41)	Monkey				
Parainfluenza type 3, hemadsorption type 1 (HA-1)	Human, guinea pig, monkey	Hamster, ferret, cotton rat, mouse, lamb	Monkey kidney, human embryonic kidney	±	In monkey cells: elongated, detachment of cell sheet In human cells: syncytial
Shipping fever (SF-4) Parainfluenza type 4	Cow, human	Hamster, guinea pig	Monkey kidney	±	Rounding granular, vacuolated

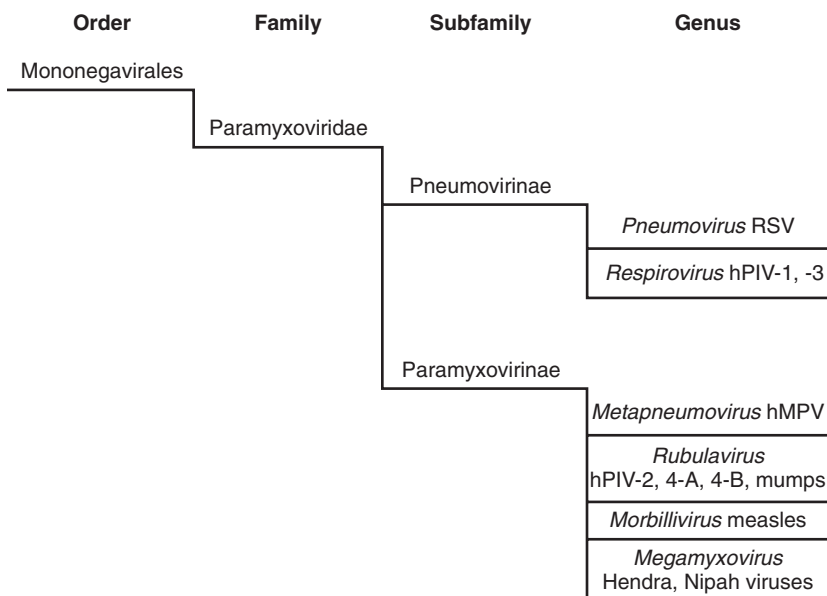

FIG. 179.1 Classification of parainfluenza viruses that cause human infection.

host cell, which is studded with spikes of surface glycoproteins, the hemagglutinin-neuraminidase (HN) and fusion (F) proteins, which are the major protective antigens. The large polymerase (L) protein and the phosphorylated nucleocapsid-associated (P) protein also form clusters within the nucleocapsid structure. The sixth structural protein is the nonglycosylated matrix (M) protein, located between the nucleocapsid and the envelope.

Replication and assembly of the virus occur solely in the cytoplasm of the host cell.^{111,197} The NP, along with the P and L proteins, is responsible for the primary transcription that occurs sequentially, beginning from the 3' end of the genome, producing predominately nonoverlapping subgenomic messenger RNAs from which the viral proteins are translated. The genome also is replicated from the formation of a full-length antigenome with positive-sense RNA. The NP and the genomic RNA make up the helical structure, and with the subsequent addition of the P and L protein complexes, the nucleocapsid is formed. The envelope proteins are assembled at the cell surface. The M protein is the smallest of the major structural proteins and is the most abundant of the virion's proteins. The M protein facilitates the interaction between the nucleocapsid and the surface glycoprotein by the attachment and insertion of the surface glycoproteins to the host cell and recruitment of the completed NP to the budding site of new virions, which are

released from the cell surface by evagination of the plasma membrane. Like the M protein of RSV and paramyxoviruses, the PIV M is responsible for reassembly of viral proteins newly synthesized in the infected cell.²²²

The HN protein is a dimer of two polypeptide portions held together by a disulfide link in the hydrophilic region and at the bases by hydrophobic bonds. The HN is the major immunogenic and type-specific determinant. It is important in multiple viral functions, including mediating the attachment of the virus to the host cell by binding to sialic acid (N-acetylneuraminic acid), a terminal saccharide receptor present on the cell glycans. The hemagglutination component of the HN protein mediates the hemagglutination of mammalian erythrocytes. The neuraminidase component of the HN protein functions during late infection to release progeny virions by dislodging the cellular bond by cleaving the sialic acid residues and prevents reattachment of the viral particles to the cell surface.

The F protein effects entry of virus by fusing the host and viral cellular membranes. Once adsorption of the virus occurs, the F protein precursor, F0, is cleaved by host proteases into the active F1 and F2 protein fragments, which mediate penetration of the virus into the cell, with subsequent fusion of the viral and cell membranes and hemolysis. The N-terminal residues of the F1 protein (the fusion peptide) promote the penetration and fusion of the virus with the cellular membrane. In

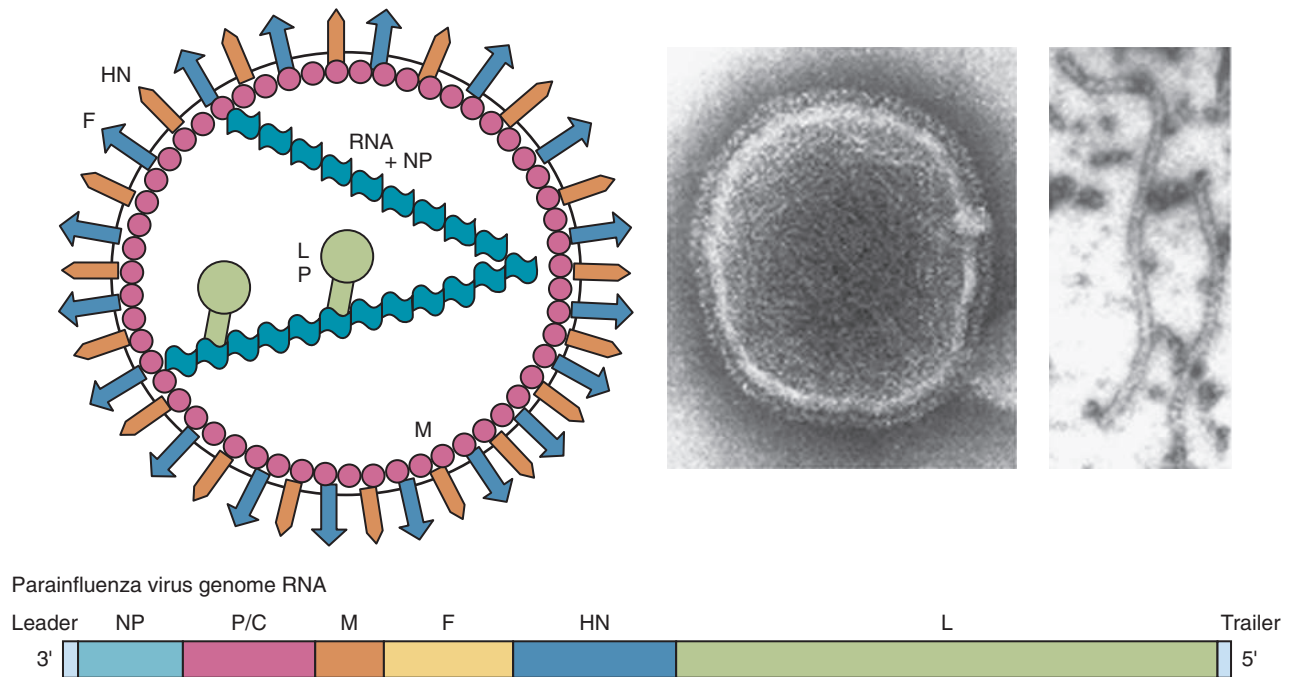

FIG. 179.2 Structure of parainfluenza virus (Sendai virus, *top left*) and its genomic RNA (*bottom*). Electron micrograph of Sendai virus (*top middle*) and its helical nucleocapsid (*top right*). (From Takimoto T. Parainfluenza viruses. In: Harper D, editor. *Encyclopedia of Life Sciences*. Chichester, UK: John Wiley & Sons; 2006:678-684.)

contrast to the foregoing proteins, the nonstructural C, V, and D proteins are not encoded by all the hPIVs but are produced variably by the different hPIV types and appear to have roles in transcription, replication, production, and pathogenicity of the virions. At least with hPIV-3, the C protein has been shown to inhibit viral transcription.^{50,89,111,134} Recent structural studies led to a better understanding of the various mechanisms by which hPIVs and other Paramyxovirinae attachment glycoproteins use cell-surface receptors to facilitate viral entry²⁶ and form particles that assemble and bud from the cellular membranes.⁸⁶

hPIVs share common antigens but also may be differentiated into two antigenic groups. hPIV-1 and hPIV-3 are within the Paramyxovirinae genus *Respirovirus*, and hPIV-2 and hPIV-4A and hPIV-4B are within the Paramyxovirinae genus *Rubulavirus*¹¹¹ (see Fig. 179.1). Their common antigenicity is illustrated by serologic heterotypic antibody responses to infection with hPIV-1, hPIV-2, and hPIV-3 and mumps viruses. Although the hPIVs do not undergo major antigenic alterations in their surface antigens similar to influenza virus, genetic and antigenic variations within all four types have been detected, and their evolution can be determined by analyses of strains obtained over time.^{89,111,220}

Isolation and Identification

The hPIVs are inactivated rapidly by acid at a pH of 3.0 and by exposure to lipid solvents, such as ether and chloroform, which destroy the envelope of the virus. They also are relatively labile to temperatures higher than 37°C (98.6°F).^{52,53} Media containing protein, however, tend to protect against loss of infectivity when the virus is exposed to heat and when it is frozen at -70°C (-94°F).^{52,98}

Isolation of the hPIVs occurs in permissive cell cultures after an incubation period of 3 to 7 days at 35° to 37°C (95° to 98.6°F). The preferred cell cultures for the isolation of the hPIVs are primary or continuous monkey kidney cells, such as LLC-MK and human embryonic kidney cells, along with a continuous line of mucoepidermoid human lung carcinoma cells, NCI-H292.^{63,89,111} The production and characteristic type of cytopathic effect in tissue culture vary according to the hPIV strain (see Table 179.1).¹⁶⁶ hPIV-1 and hPIV-3 on initial isolation are unlikely to demonstrate distinctive cytopathic effects, but, depending on the cell line, they may on passage. hPIV-4 is the most difficult hPIV to grow and identify in tissue culture because the cytopathic effect is not evident, and 2 to 4 weeks may be required before identification by hemadsorption is

possible. Identification of hPIVs in tissue culture traditionally has relied on the ability of the hPIVs to hemadsorb erythrocytes, most commonly guinea pig, human group O, or chicken erythrocytes, at 4°C or 25°C (39.2°F or 77°F). However, the sensitivity of this method is variable, especially for the rubulaviruses hPIV2 and hPIV4.⁸⁹

EPIDEMIOLOGY

Geographic Distribution

The ubiquitous nature of the hPIVs has been illustrated among diverse populations, in many parts of the world, and in differing climates.^{68,139,144,156,193,211} Despite these wide variations, experience with the hPIVs is similar in most countries.

Prevalence and Age at Infection

The frequency and impact of hPIV infections are greatest among preschool-aged children and are estimated to account for approximately one third of the lower respiratory tract infections in this age group.^{68,89,92,119,173} Among the hPIVs, the type most commonly isolated is hPIV3, which usually is acquired first, followed by hPIV-1 and hPIV-2 (Fig. 179.3).

Like RSV infection, hPIV-3 infection is a common occurrence during the first few months of life. Half to two thirds of infants have acquired infection by the time they reach 12 months of age.^{68,144,148} Experience with hPIV-1 and hPIV-2 usually occurs later, most commonly during the preschool years.^{68,69,144,173} In a study in Tecumseh, Michigan, the annual isolation rate of hPIV per 1000 person-years was 53.8 for children birth to 4 years of age, 14.3 for those 5 to 19 years of age, 3.9 for adults 20 to 39 years of age, and 2.3 for those 40 years of age or older.¹⁴³

The frequency of hPIV infection among young children was well illustrated by the Houston Family Studies, in which infections were detected by both viral isolation and serology among children observed from birth.^{68,69} By the time they reached 2 years of age, 92% of the children had experienced at least one infection with hPIV-3 and 32% had been infected more than once. hPIV-3 is the most frequent cause of hospitalizations associated with hPIV infections. hPIV-1 and hPIV-2 are associated primarily with hospitalizations of children 2 to 6 years old. The age distribution of children with hPIV-1 and hPIV-3 viral infections cared for in private pediatric practices, however, may overlap substantially (see Fig. 179.3). Among outpatients in Rochester, New

FIG. 179.3 Age distribution of infections with human parainfluenza virus types 1, 2, and 3 in outpatient children in Rochester, New York, from 1976-1992. (From Knott A, Long CE, Hall CB. Parainfluenza viral infections in pediatric outpatients: seasonal patterns and clinical characteristics. *Pediatr Infect Dis J.* 1994;13:269-273.)

York, approximately half of the hPIV-3 viral infections occurred among children younger than 24 months, in contrast to approximately one third of the hPIV-1 infections.¹¹⁹ Among children 2 to 5 years of age, the reverse was true, with half of the hPIV-1 infections and approximately one third of the hPIV-3 infections occurring in this older age group.

Until recently, the epidemiology of hPIV-4 was less well described, in part because the clinical disease is mild and its recovery from cell cultures is inherently low, and thus its prevalence was underestimated.^{122,123,178} More recent studies using sensitive reverse transcription polymerase chain reaction (RT-PCR) methods show that hPIV-4 infection is more frequent and sometimes can cause more serious illnesses than previously recognized.^{31,60,210} Serologic studies have suggested that infection with hPIV-4 is particularly frequent during the preschool years, with between 50% and 90% of 5-year-old children possessing antibodies.^{117,123,124}

Seasonal Occurrence

The seasonal patterns of the hPIVs vary according to location and year. In temperate regions, the incidence of parainfluenza viral infections appears to correlate with seasonal weather conditions, but in tropical regions it is less well defined. Different hPIV strains have different seasonal activities.⁶⁴ hPIV-1 tends to occur in the fall and commonly causes outbreaks of croup every other year.^{68,114,173} The behavior of hPIV-2 has been more erratic.^{68,89,119,173} During 20 years of surveillance in Rochester, New York, hPIV-2 appeared sporadically and in low numbers of cases, usually at the end of the fall outbreaks of hPIV-1 in the odd-numbered years.^{80,119} hPIV-3 may be present in a community in case numbers for many months, but swells of more epidemic activity occur in the spring to fall.^{68,80,119} During long-term surveillance, approximately 75% of hPIV-3 isolates were recovered in the spring and summer and most of the remainder were obtained in the autumns of the even-numbered years, when hPIV-1 was absent.¹¹⁹ hPIV-4 usually occurs during late fall and winter in temperate countries,^{123,124} but in China it is more prevalent during the spring and summer.¹⁷⁴ Studies from a more diverse geographic range are needed to better understand the global seasonal patterns of hPIV-4.

PATHOGENESIS

Transmission

Experimental studies using Sendai viruses have shown that even a low inoculum (70 plaque-forming units) to the upper respiratory tract resulted in robust growth and efficient contact transmission.²⁹ Of note, the efficiency and timing of transmission were independent of clinical symptoms and severity, which is consistent with data from animal models and with the epidemiology of hPIV outbreaks.^{80,89} Furthermore, more severe infection involving the lower respiratory tract was a poor predictor of transmission.²⁹ Several clinical and experimental observations also have indicated that the hPIVs are able to spread readily

and effectively.^{7,47,84,107,148} Close contact with infected individuals or their secretions appears necessary, which suggests infection is spread through aerosols of large particles (>10 μ m mass median diameter) that travel short distances (<0.9 m) or by touching infectious secretions on fomites followed by self-inoculation.⁸¹ Contagiousness, therefore, is related to how effectively the infectious secretions are propelled into the environment, such as through sneezing and coughing, and how well the infectious virus can survive in the environment.²⁷

Children with primary infection caused by hPIV-1 have considerable quantities of infectious virus in their nasal secretions, an average of approximately 1000 tissue culture infective doses (TCID₅₀) per milliliter.⁸⁴ Because hPIVs cause illnesses associated with frequent sneezing, coughing, and profuse nasal discharge, transmission and environmental contamination of infectious secretions is likely to occur readily, especially among young children. Although the routes of inoculation that occur naturally have not been studied adequately, adults have been infected experimentally by intranasal and oropharyngeal inoculation. The eye as a site of inoculation has not been examined similarly, but it may be an important portal of infection from self-inoculation with contaminated hands.

Experimental data suggest that hPIV secretions survive well on hard, nonporous surfaces, such as those found in hospitals, workplaces, and homes. The hPIVs remain infectious on nonporous surfaces for as long as 10 hours and on porous surfaces for as long as 4 hours, but survival may be diminished by drying.²⁷ hPIVs may remain infectious after being transferred to hands from environmental surfaces, a finding further suggesting that fomites are an important mode of dissemination. A curious conundrum is the survival and persistence of hPIV-1 and hPIV-3 infections among a group of individuals isolated in the frigid environs of the South Pole for 8.5 months.^{147,161} Despite no outside contacts, infection with hPIV-1 and hPIV-3 occurred repetitively in the quarantined individuals. This phenomenon raised the possibility that persistent infection may be engendered not only in tissue culture but also in humans under such circumstances as extreme environmental conditions.

Pathology

Inoculation of the hPIVs into the upper respiratory tract results in infection of the nasal epithelium and nasopharynx and the appearance of clinical signs after an incubation period of 2 to 4 days. The hPIVs appear to replicate preferentially in the superficial ciliated epithelial cells lining the airways of the upper and lower respiratory tract. The factors determining the tropism and severity of the viral infection are incompletely understood. Such factors may include host genetics, age, and immunity; the protease activity of various tissues; and virus-specific determinants, such as the cleavage phenotype of the F₀ protein.^{111,145}

The magnitude of viral replication appears important in the pathogenesis, as evidenced by the correlation of viral loads with severity of disease.^{24,78,81} This has been confirmed by the development of live attenuated PIV vaccines using reverse genetics, which demonstrated precise viral mutations correlated with clinical attenuation.^{18,55,108,155} Viral shedding is most abundant and prolonged in young children with primary and severe disease and may begin several days to a week before the onset of symptoms.⁸⁴ Children with hPIV-1 infections shed the virus for an average of 4 to 7 days, but may shed for as long as 12 days. With hPIV-3 infections, shedding tends to be longer, occasionally for 2 to 3 weeks, and in adults with chronic lung disease, shedding may be both prolonged and intermittent.^{77,87}

The pathophysiology of hPIVs has been explored in animal models.^{111,159,170} Inoculation of rodents with hPIV-3 produced histologically evident, but usually asymptomatic, interstitial pneumonitis or bronchiolitis. Ferrets also can be silently infected, but in newborn ferrets, PIV infection may be progressive and fatal.¹⁴² Chimpanzees and several species of monkeys may be infected, but clinical manifestations generally are lacking, except with hPIV-3 infection of chimpanzees and African green monkeys.²⁰¹ Inoculation of hPIV-2 into the respiratory tract of a canine model produced clinical signs of cough and rhinitis accompanied by histologic changes in the airways.¹¹¹

Pathologic studies of children with hPIV infections are limited. The few cases of confirmed hPIV infection examined have shown that in the young child with primary infection, inflammation, marked primarily by necrosis of the epithelium, is evident throughout the respiratory

tract. The subglottic tissues in croup appear particularly involved, but with primary infection, the conducting airways at all levels and the alveoli may be affected.^{37,224} Lung tissue samples from 200 young children who died from severe respiratory disease, which were examined for hPIV types 1, 2, and 3, RSV, influenza, and adenoviruses, showed no distinctive histologic changes that would allow identification of a specific virus.⁵⁴ hPIV was identified as the sole pathogen in 4% of the 200 samples tested and was the sole pathogen in 10% of virus-positive samples. Of the hPIVs identified, hPIV-3 was the most common serotype. hPIV infections caused bronchopneumonia and interstitial pneumonitis, which had infiltrates consisting mainly of mononuclear inflammatory cells in the bronchial lumen. Most of the children with bronchopneumonia had cellular necrosis and destruction of the bronchial pseudostratified columnar epithelium and diffuse alveolar damage. Immunohistochemical assessment on tissue microarray slides showed the virus in bronchial and bronchiole epithelial cells and in alveolar cells.⁵⁴

IMMUNE RESPONSE: ROLE IN PATHOGENESIS AND PROTECTION

Innate immunity's role in controlling PIV infection and how it is elicited are of increasing interest, but data are currently of limited clarity. Better understanding of the pathogenesis of the innate response and its effect on the transition to adaptive immunity may lead to novel and better means of controlling the ubiquitous hPIV infections that occur during infancy and thereafter.

The innate antiviral responses to infection of viruses of the Paramyxoviridae family have been studied in experimental models. The response is elicited within the respiratory tract once the viral genome enters and replicates in the cytoplasm of the host cell and is characterized by the production of a cascade of immunomodulatory mediators, chemokines, and proinflammatory cytokines.^{49,67,111,157,158} Toll-like receptors (TLRs), a class of pattern-recognition receptors, appear to be important early in the innate antiviral defense.^{49,140} The products of viral replication trigger and activate specific TLRs that allow the binding of the virus to the host cell and the expression of the genes associated with the host immune response. TLRs may help mediate the immune response, both by their interaction with infected respiratory epithelial cells and by the induction of dendritic cell maturation that is integral in the subsequent development of adaptive immunity with the production of effector and memory T cell and B cells.^{128,180} Although TLRs appear to have a pivotal place in innate antiviral defense, experimental evidence suggests that replicating infection of paramyxoviruses and other respiratory viruses may induce and enhance the innate immune response by other pathways that are not dependent on TLR-mediated signaling.^{126,128,130}

The major components of the adaptive immune response to hPIV infection that play important and independent roles in primary infection and reinfection are both humoral and cellular. Rodent models using Sendai virus have shown that CD8⁺ cytotoxic T lymphocytes are necessary for clearing the virus from the lung.^{96,115} The viral antigen is carried by dendritic cells and macrophages to the draining lymph nodes, and activated cytotoxic T lymphocytes subsequently migrate to the site of pulmonary inflammation, resulting in viral clearance. The cellular immune response of memory T cells, which was established during the primary infection, persists in high titers in the spleen and rapidly responds to a repeated infection. In addition, virus-specific interferon (IFN)- γ -producing CD4⁺ T cells have been shown to increase in the airways of infected mice during viral clearance, and IFN- α and IFN- β may be produced by experimental PIV infection.^{74,83,111} IFN production also has been demonstrated during natural parainfluenza infection in young children.^{87,219} However, some hPIVs may be able to evade this protective response by inhibiting IFN production through accessory proteins (C and V) expressed from the P gene.^{25,74,111,116}

In contrast to infection with hPIV-1 and hPIV-2, the most serious illness caused by hPIV-3 infection usually occurs during the first year of life, when infants possess maternally derived specific antibody. This finding has raised the question of whether interactions of maternal antibody and virus may be detrimental.¹³⁹ In animal models, however, passively administered PIV antibody and monoclonal antibodies against the F and HN proteins appeared protective. Furthermore, the trials with

an inactivated trivalent hPIV vaccine in the 1960s did not suggest a pathogenic role for antibody.⁶⁶ Although not protective, the vaccine was immunogenic and produced serum antibody in the vaccinees. Subsequently, the vaccinees did not experience augmented disease, as observed with the simultaneously tested formalin-inactivated RSV vaccine.

In animal models the specific antibody response is generated only during the later phase of the primary infection and does not play an important role in clearing the infection.²²³ However, specific antibodies are protective against secondary challenge with the same parainfluenza virus. Clinical observations also show that the more severe infections involving the lower respiratory tract occur during initial infection in young, seronegative children, but recurrent infections usually are mild. Naturally acquired immunity, therefore, although not complete, and of variable durability, does provide protection against more severe disease.^{69,111} Antigenic variation in the hPIVs is not sufficient to explain the lack of complete or durable immunity. The cause is more likely the waning of both humoral and cellular immune responses that occurs during the intervals between exposures to one of the hPIVs.

Serum hemagglutination-inhibition antibody and neutralizing antibody are detectable within 1 to 2 weeks.¹¹⁴ Neutralizing antibody is directed primarily to epitopes on the HN and F proteins. The importance of neutralizing antibody in providing protection against infection of the lower respiratory tract, and to some extent of the upper respiratory tract, has been well established in animal models. Infants with primary hPIV infection usually produce a greater antibody response toward HN than F, and the response is relatively specific to the PIV serotype. With repeated infections, an anamnestic and broader humoral antibody response occurs, producing antibodies with cross reactivity against the different hPIV serotypes. In young children with primary hPIV-3 infection, the antibody response to the HN protein has been shown to be directed at multiple neutralizing antigenic sites.²⁰² The response to the F protein, whether with primary or recurrent infection, appears to be more variable in magnitude and restricted in terms of antigenic sites. The presence of maternal antibody, however, inhibits the infant's ability to produce specific humoral antibody.

Primary and secondary infections result in secretory immunoglobulin (Ig)G, IgM, and IgA antibodies that peak at 2 weeks after onset of symptoms.^{49,219} Infection induces relatively incomplete protection in infants because of the lower titer of antibodies and the different IgG subclasses produced.⁴⁹ IgG₁ and IgG₃ antibodies are the predominant subclasses, contrary to the IgG₂ antibodies generated in older children and adults. Protection of the upper respiratory tract is mediated by secretory IgA and that of the lower tract by local IgG antibodies.⁴⁹ The transient nature of the induced secretory IgA antibodies may partially explain the common occurrence of reinfections throughout life.

Understanding the cell-mediated immune response to hPIV infection is important for vaccine development, and observations about the functions of CD4⁺ and CD8⁺ T cells in the recall response to PIV infection suggest that this system plays a major role in protection from primary and recurrent infections.^{189,217} The increased severity and prolonged period of viral shedding in immunocompromised hosts, such as those receiving organ transplants, indicate the importance of intact cellular immunity in the control of disease and recovery from hPIV infection.^{39,58,203}

CLINICAL MANIFESTATIONS

Primary Infection

The types of illnesses caused by hPIV infections have characteristic associations with the age of the child, the season, and the hPIV serotype (see Figs. 179.3 and 179.4).^{69,71,100,119,124,173,211,218} Most primary infections are symptomatic, and many affect the tracheobronchial and lower respiratory tract. Of the primary infections that involve only the upper respiratory tract, fever and laryngeal or tracheal signs are common occurrences. Even an influenza-like illness with sudden onset of high fever, chills, cough, headache, myalgia, or fatigue has been reported to occur with hPIV infection.^{168,184} Reinfections occur frequently at all ages and usually are mild and limited to the upper respiratory tract, or sometimes they are asymptomatic.⁶⁹

The hPIVs cause a greater proportion of acute respiratory tract illnesses among outpatients than among hospitalized children.^{119,124} Of

FIG. 179.4 Clinical manifestations of parainfluenza virus infections according to serotype in pediatric outpatients in Rochester, New York (1976–92). *LRI*, Lower respiratory tract infection other than croup; *URI*, upper respiratory tract infection (including otitis, colds, and pharyngitis). (From Knott A, Long CE, Hall CB. Parainfluenza viral infections in pediatric outpatients: seasonal patterns and clinical characteristics. *Pediatr Infect Dis J*. 1994;13:269-273.)

all viral respiratory illnesses examined in a pediatric practice, the hPIVs caused approximately two thirds of the croup cases, one fourth of the tracheobronchitis cases, and approximately half of the upper respiratory tract illnesses, including colds, laryngitis, pharyngitis, and otitis media.

hPIV infections account for almost 7% of all hospitalizations for respiratory illnesses with or without fever among children younger than 5 years of age.²¹¹ The proportion of children with hPIV infection who require hospitalization, mainly those with croup, has markedly diminished in recent years, primarily because of better outpatient management and therapy of croup (see discussion of [management and therapy](#)).^{185,218} Currently, most children hospitalized with hPIV infections are infants with pneumonia and bronchiolitis from hPIV-3, who are most likely to be admitted during the spring. hPIV infections may cause 11% of admissions for virus-induced asthma attacks; fatalities are uncommon, but may occur.⁴ Pneumonia has been described with hPIV infections in previously healthy adults, such as among military recruits, but has been considered to be uncommon in normal, healthy populations of adults and school-aged children.^{59,212} However, hPIV types 1 through 3 account for 4% to 6% of community-acquired pneumonias among adolescents and adults.¹⁷¹ As many as 20% of pneumonias occurring in children in lower socioeconomic circumstances are caused by hPIV.¹⁰² In contrast, hPIV infections in children are asymptomatic in less than 2.2% of cases.⁹⁷

The onset of the typical primary hPIV infection generally is acute and associated with mild fever and upper respiratory tract signs of the common cold, such as rhinitis, sore throat, and cough. Laryngeal involvement manifesting as hoarseness is apt to be more prominent than with other viruses that commonly produce colds in young children. After 3 to 4 days, these upper respiratory tract symptoms may progress, primarily in infants with hPIV-3 infection, to involve the lower respiratory tract. The characteristic manifestations of pneumonia or bronchiolitis, including dyspnea, crackles, wheezing, and hyperaeration, follow. Children with hPIV-1 or hPIV-2 infection, who usually are 2 years of age or older, also have acute onset of fever and upper respiratory tract signs, but if the infection progresses in this age group, it is more likely to evolve into croup. Children with hPIV-1 infections who were seen in a private pediatric practice during a community outbreak of hPIV-1 predominantly had fever, upper respiratory tract signs, and tracheobronchial or tracheolaryngeal signs of croup.⁸⁴

In children with croup, upper respiratory tract illness is generally present for 2 to 3 days before the patient abruptly (and usually at night) develops markedly increased work of breathing. The classical “croup triad” (barking cough, stridor, and laryngitis) distinguishes croup from other illnesses. Patients may also exhibit nasal flaring, retractions of the chest wall, and dyspnea.¹⁹² The course of croup varies, with lessening in the intensity of the stridor and dyspnea during the day, with return of symptoms (usually of lesser severity) in the ensuing evenings. The acute symptoms usually last for 3 to 4 days, although cough may continue

for longer.²³ Fewer than 10% of children with croup have hypoxemia from viral involvement of the lung parenchyma, which, although important in management, may not be recognized because of the focus on the apparent major site of inflammation, the subglottic area. Because obstruction occurs in the subglottic area, marked CO₂ retention may occur in the absence of significant hypoxia. The most reliable findings to assess illness severity are the severity of stridor and the degree of retractions.^{35,40} Very few patients need intubation in the era of high-dose dexamethasone therapy, and the mortality is low.¹⁷⁷ Recurrent (spasmodic) croup usually occurs without fever or other respiratory tract symptoms. It has a viral etiology similar to that of acute laryngotracheobronchitis,²⁰⁹ but allergic reactions or gastroesophageal reflux may cause a somewhat similar syndrome.⁴⁰

Otitis media may complicate hPIV upper respiratory tract infection among young infants and older children.^{42,88,119,146,172,213} hPIVs are commonly isolated from children with and without a history of otitis media, and thus their role in acute and recurrent otitis media is unclear. However, of the otitis media cases that have been associated with hPIV, the serotypes most frequently identified were hPIV-1 and hPIV-3. hPIVs have also been detected in middle ear aspirates as the sole agent or with a bacterial agent, suggesting that hPIVs may play both primary and secondary roles in predisposing children to middle ear infection.

The association of acute hPIV infection with a nonrespiratory illness or the isolation of hPIV from sites other than the respiratory tract occurs rarely. Case reports have associated hPIV infections with a variety of diseases, including adult respiratory distress syndrome, pertussis-like disease, parotitis, myopericarditis, and diseases of the central nervous system.^{9,50,95,101,121,206,215} Anecdotal reports also have associated hPIV infection with collagen vascular diseases and sporadic severe hepatitis, characterized histologically by syncytial giant hepatocytes.^{164,165}

The clinical manifestations associated with hPIV-4 are less well described, which may be explained partially by the technical difficulty of isolating hPIV-4.^{31,60,93,123,127,210} Most have been associated with a mild, usually afebrile upper respiratory tract infection, but more severe disease and lower respiratory tract illness also have been reported.¹²⁷

Reinfection

Immunity to PIV infection is transient and incomplete; therefore, reinfections commonly develop among healthy older children and adults. hPIV reinfections usually are mild, with symptoms of the common cold. In adults, hPIV-1, hPIV-2, and hPIV-3 cause approximately 2% to 5% of the upper respiratory tract infections, but one fifth or more of these infections may be asymptomatic.^{24,93} Of those with clinical illness, approximately 30% to 92% develop fever, which is often associated with malaise, sore throat, and cough. Rhinorrhea occurs in fewer than 25% of infections among adults and usually less among children.

hPIV infection may cause more severe disease in elderly persons and also may exacerbate symptoms in both children and adults with

chronic lung disease, including chronic bronchitis, asthma, and cystic fibrosis.^{46,70,106,153,199,200}

Infection in Immunocompromised Patients

As demonstrated by multiple reports of outbreaks of hPIV infections occurring on transplant units, children and adults with compromised immunity, especially those with deficient cellular immunity, are at high risk for development of severe, and sometimes fatal, hPIV disease.^{22,39,58,125-137,167,203,205} Some of these hPIV outbreaks are not associated with a concurrent increase in hPIV infections in the community, which suggests that many hPIV infections are nosocomial.^{125,152} Most of the hPIV infections occur more than 1 year after transplantation. Close to half of the hPIV infections involve the lower respiratory tract, and approximately 15% to 40% of these infections are fatal.^{15,204} Improved survival may accompany better supportive care, and better screening for hPIV infection.¹⁹⁶ In some studies, hPIV infection is as common as RSV infection in causing pneumonia in these patients.³² Corticosteroid administration for graft-versus-host disease (GVHD) increases the risk for developing lower respiratory tract infection.¹⁵¹ Recipients of non-myeloablative conditioning regimens appear to have a lower risk for developing lower respiratory tract disease.¹⁸²

Very high viral loads have been found in bone marrow transplant patients with pneumonia,³² and the duration of shedding of hPIV is prolonged. These two features significantly augment the risk for an outbreak of infection among patients and personnel in transplant units. Furthermore, hPIV infection often is not considered among the opportunistic infections that plague these patients, and the diagnosis is confounded by the observation that hPIV infection may lead to bacterial and fungal pneumonia.^{56,151} In addition, the sensitivity of detecting the virus in specimens from the upper respiratory tract is poor.

The incidence of hPIV infections among lung transplant recipients has been estimated to be 1.6% to 11.9% and is most often associated with hPIV-3.^{203,205} Among these patients the initial manifestations of hPIV infections are usually nondistinctive upper respiratory tract symptoms, such as cough and sore throat, and, less commonly, rhinorrhea and fever.²⁰³ Progression to involvement of the lower respiratory tract or rejection of the transplant follows in approximately 10% to 70% of cases, depending on multiple host factors, including being a child, presence of GVHD, degree of immunosuppression, and corticosteroid or antilymphocyte therapy.^{99,198} The risk for developing lower airway disease in transplant recipients is further enhanced because of mechanical factors present in transplanted lungs and because of altered or absent mucosal immunity.²⁰³ The bronchus-associated lymphoid tissue in the lung, which is integral to the protective immune response against pulmonary infections, is injured during transplantation, thus resulting in diminished control and clearance of the viral infection.

Therefore, the high rate of symptomatic infection (95%) with hPIV infections among lung transplant recipients is not surprising.²⁰³ Cough has been reported as present in 70%, dyspnea in 66%, fever in 16%, and lower respiratory tract disease, which is diagnosed as viral pneumonia, in 16%. hPIV and other viral infections may lead not only to graft rejection but also to severe long-term complications. Thirty-two percent of lung transplant recipients have developed acute bronchiolitis obliterans, which has occurred an average of 6 months (range, 1 to 14 months) after their hPIV infection.^{58,203,204} hPIV infection occasionally has been reported also to be complicated by pancytopenia, Guillain-Barré syndrome, parotitis, and acute disseminated encephalitis.^{10,121,176}

Among children with immunodeficiency syndromes who have diminished cellular immunity, especially children with severe combined immunodeficiency syndrome, hPIV has been notably severe and frequently fatal.¹⁰⁴ Complicated disease and lower respiratory tract involvement are observed less frequently with hPIV infection among children with less severely compromised cellular immunity, such as patients with human immunodeficiency virus (HIV) infection.^{109,132,141} The clinical severity of hPIV infection among patients with HIV infection is variable, but even among those with mild disease, the shedding of hPIV usually is prolonged and may persist beyond the period of clinical symptoms.

DIAGNOSIS

The diagnosis of hPIV infections may be surmised on clinical and epidemiologic grounds, such as the patient's age, the type of illness, and the seasonal patterns of hPIV in the community. However, the nonspecific clinical presentation of many other viral respiratory infections makes the specific laboratory diagnosis of hPIV necessary. During the acute phase of the illness, hPIV may be diagnosed in specimens of nasal secretions by the following methods:

1. Detection of viral RNA using RT-PCR in single or multiplex assays.^{2,16,214} RT-PCR has markedly increased the detection and specific identification of the hPIVs in patient specimens.^{28,89,91,211} RT-PCR assays can detect a single respiratory virus or multiple viruses simultaneously and provide sensitive, specific, and rapidly available identification of hPIVs from clinical specimens.^{30,160,214}
2. Isolation of the virus by culture or enhanced by shell viral culture techniques.¹⁶⁶
3. Serologic assays during the patient's convalescence (see discussion of **isolation and identification**).

Numerous serologic assays exist, including complement fixation, hemagglutination-inhibition, hemadsorption inhibition, neutralization, enzyme immunoassay, and immunofluorescence.^{61,90} However, serologic diagnosis is confounded by heterotypic antibody responses (see discussion of **immune response**). During reinfection, both homotypic and heterotypic antibody rises may occur, or sometimes little antibody response is detected, despite shedding of the virus from the nasopharynx.¹¹¹ Less is known about the antibody response to hPIV-4 infection, but during primary infection, a homotypic response usually occurs.¹¹⁷ Detection of specific IgM antibodies, which usually persist for 2 to 11 weeks after infection, has been of limited success as a diagnostic technique.²⁰⁷

PCR-based methods should be the preferred diagnostic tool for hPIV infection over culture or serologic assays because they have a sensitivity of 95% to 100% and a specificity of 97% to 100% in contrast to viral isolation.^{8,89} Although most hPIV infections do not require specific diagnosis, among more severely ill and hospitalized patients the diagnosis using these newer molecular techniques, if rapidly available, offers several advantages in addition to their high sensitivity and specificity. Among these are giving the health care provider a known specific viral diagnosis, diminished use of unnecessary antibiotics, and the implementation of effective infection control procedures, potentially reducing the risk for nosocomial infection with a different virus from patients with the same clinical presentation.

Differential Diagnosis

Most of the other major respiratory viral pathogens can mimic the illnesses produced by hPIV infections. Clinical differentiation rarely is possible. More helpful are such epidemiologic clues as the differing seasonal patterns and age-related attack rates of the common viral agents of respiratory illnesses in children.⁸²

Croup from hPIVs or any other virus must be differentiated from bacterial tracheitis, retropharyngeal abscess, and epiglottitis, which have rapidly progressive courses and a potentially fatal outcome. With the widespread use of the *Haemophilus influenzae* type b vaccine, epiglottitis now occurs very rarely. Reports of epiglottitis have not been published in the past 10 years. Retropharyngeal abscess is also less common because of the widespread use of antibiotics for upper respiratory tract infections. However, bacterial tracheitis has been occasionally observed, usually as a complication of refractory hPIV croup, in which the patient is being intubated for respiratory failure.⁹⁴

Children with croup associated with hPIV infection usually have peripheral white blood cell counts that are normal or initially slightly elevated, with a mild left shift. In contrast, among children with stridor from epiglottitis, retropharyngeal abscess, or bacterial tracheitis, the left shift usually is marked.

In countries that continue to have diphtheria, laryngeal diphtheria may be a consideration in an unimmunized child. However, laryngeal diphtheria usually is gradual in onset and manifests with characteristic membranous pharyngitis. Stridor and other signs of croup also may be present in children with congenital or acquired conditions that

obstruct the laryngeal airflow, such as aspiration of a foreign body, tracheomalacia, stenosis, and acute angioneurotic edema.

MANAGEMENT AND THERAPY

Most hPIV infections are self-limited and require no treatment. Specific therapy currently is not available for hPIV infections. In vitro studies have shown that ribavirin inhibits hPIV, but clinical studies produced mixed results. A few small studies showed some benefit in controlling hPIV infections among a limited number of immunocompromised patients,^{34,45,57,138,194} but larger studies have not shown such an effect, and the duration of viral shedding was not shortened.^{56,151} Controlled trials, however, are lacking. Thus, until more data are available, aerosolized ribavirin currently should be considered only for high-risk patients with severe lower respiratory tract disease. Among potential therapies being explored are sialic acid inhibitors, such as those used for treating influenza, which inhibit hPIV F and HN activities.^{2,76,150,169} Other therapeutic approaches include interference with viral attachment and replication with the use of inhibitors of protein and nucleic acid synthesis, synthetic peptides, and antivirals inhibiting S-adenosyl-L-homocysteine hydrolase^{19,89,111,197} or protein kinase B (AKT), which is critical for viral replication.⁶⁵

Management of croup in the home is primarily supportive.²¹⁸ The armamentarium used during the past century has been varied and usually anecdotal, ranging from cold night air to humidification or putting the child in a comfortable position. No such home therapies have proved beneficial. Simply holding the child may relax them, lessening the degree of dyspnea.

Children who are more severely affected require outpatient evaluation, usually in an emergency department. With the current management offered in emergency departments, few children's symptoms progress such that hospitalization is required.^{48,185,218} Intravenous immunoglobulin (IVIG) is not recommended; a retrospective analysis of its administration did not find any benefit.¹⁵¹ The current consensus and recommendations for the management of acute viral laryngotracheitis have afforded a more consistent beneficial outcome.^{3,40,218} Administration of 0.05 mL/kg (maximum, 5 mL) nebulized 2.25% racemic epinephrine (a 1:1 mixture of D- and L-isomers of epinephrine) has been demonstrated to provide rapid relief for the airway obstruction. The relief from nebulized epinephrine is transient, usually lasting no longer than 2 to 3 hours; however, this is often long enough to allow for the onset of activity of corticosteroids. Patients who improve after receiving racemic epinephrine should be observed for at least 3 hours after the last racemic epinephrine dose, to be sure that illness does not return as the effect of the aerosol wears off. Furthermore, hypoxemia, if present, and the outcome are not affected by treatment with nebulized epinephrine.^{188,218}

Administration of corticosteroids has become the cornerstone of management for the more severely affected child who fails to improve with the usual supportive care. Corticosteroids administered intramuscularly, intravenously, or orally have been shown to provide significant and lasting benefit on the clinical course and outcome, in contrast to placebo or other therapies, and also decreased the need for nebulized epinephrine.^{3,5,179} Although studies have shown that any dexamethasone dose between 0.15 mg/kg and 0.6 mg/kg (with a maximum of 10 mg/day) will be effective in relieving the symptoms and diminishing the severity of disease and need for hospitalization,^{44,103} the recommended dose most commonly used is a single dose of dexamethasone 0.6 mg/kg given intramuscularly or intravenously.^{179,218} Prednisolone 1 mg/kg is less effective than dexamethasone 0.15 mg/kg, probably because of its shorter half-life (36 hours vs. 54 hours, respectively).¹⁹⁵ Although nebulized steroids (e.g., budesonide) have been shown to be effective, they are expensive and less effective than oral dexamethasone.³³ The treatment of croup is discussed more thoroughly in Chapter 18. Antibiotic therapy should be reserved for documented episodes of secondary bacterial tracheitis.

PROGNOSIS

Most previously healthy children recover from hPIV infections completely and without complication. Follow-up studies of normal children with hPIV infections support the generally good prognosis. Some children

who have had croup have pulmonary function abnormalities detected subsequently, but proof that these abnormalities were caused by their hPIV infection is lacking.^{79,129}

The potential for development of acute complications, morbidity, and mortality is related to the presence of a comorbid condition such as immunodeficiency and diseases that affect cardiopulmonary function, including congenital malformations and acquired conditions obstructing the airway.²¹⁸ Of children hospitalized with hPIV infections who were studied during a 4-year period, 35% had preexisting pulmonary or cardiac abnormalities, prematurity, or asthma.⁸⁷ In contrast to the children who previously were normal, the children with underlying conditions had significantly more severe disease and more complicated courses requiring longer hospitalization. Immunodeficient patients, as described previously, have particular difficulty in controlling and clearing hPIV infections; thus, these children have complicated, prolonged, and recurrent respiratory tract infections. Prolonged or persistent infection with hPIVs, especially with hPIV-3, has been noted to occur in some patients with chronic bronchitis, possibly related to the lack of a sufficient specific antibody response in the sputum.⁷⁷ The possibility that hPIV may cause central nervous system involvement has been suggested by the occasional detection of such viruses in the central nervous system in patients with previous transplantation, but there is little evidence for an hPIV encephalitis in otherwise healthy subjects.^{10,176}

Short interfering RNA (si-RNAs) that bind to messenger RNA of the virus-infected host cell are logically attractive candidates for therapy of infections caused by hPIV and other viruses, but their use is largely theoretical at this time.¹²

PREVENTION

Infection control measures to prevent the spread of hPIV through direct contact with fomites or other infected objects are integral in preventing infection. Hand washing and droplet precautions should be implemented as soon as hPIV infection is suspected and continued throughout the period of shedding, which in immunocompromised patients may be for extended periods (>100 days).⁵⁶ Nonetheless, infection control measures may fail because many hPIV infections are mild, and prolonged asymptomatic shedding may occur among immunocompromised patients¹⁶³ and adults with chronic bronchitis.

For decades, attempts to prevent hPIV infections have focused on the development of effective vaccines. The current lack of a licensed vaccine for hPIV infections attests to the problematic nature of infection with hPIVs and of the response of the human host at different ages. Many of the hurdles encountered in the development of an effective vaccine for hPIV are similar to those for RSV. The vaccine, at least for hPIV-3, would have to be administered during the first few months of life when the infant's immunologic system is not fully developed^{51,221} and when the potential inhibitory effect of passive maternal antibody exists. Furthermore, to elicit durable protection, the vaccine would have to produce an immunologic response superior to that derived from natural infection, because recurrent infections occur throughout life.

Hence, the goals of immunization for hPIVs, like those for RSV, currently may need to be modified toward prevention of more serious disease and attenuating disease associated with primary infection and reinfections by restricting viral replication. Because the greatest clinical and economic burdens have been estimated to occur with hPIV-3 infection among infants, compromised patients, and elderly individuals, many of the candidate vaccines have been aimed at providing protection against hPIV-3 infection.^{5,55,149,197}

Initially formalin-inactivated, parenteral hPIV vaccines, along with formalin-inactivated vaccines for RSV, were developed and evaluated in clinical trials.^{41,66,118,191} In general, these vaccines, whether monovalent, trivalent, or combined with other respiratory vaccines, were immunogenic, inducing a variable humoral and mucosal antibody response, but they were not protective.^{41,66} In many cases the serum antibody titers were insufficient, and nasal neutralizing antibodies were not induced.¹⁹¹

Development of candidate vaccines currently focuses primarily on live-attenuated and subunit vaccines.^{55,75,190} Live-attenuated vaccines, in contrast to inactivated or subunit vaccines, have the potential advantages of inducing immunity by more closely mimicking natural

infection by eliciting both humoral and mucosal immunity and a longer duration of protection. Furthermore, because significant yearly antigenic change, as observed with the influenza viruses, does not occur with hPIVs, a single monovalent or polyvalent vaccine may suffice, although later booster doses may be required. The potential disadvantages of a live vaccine are more adverse or symptomatic reactions, the possible transmission of the vaccine virus, and insufficient genetic stability to prevent reversion to the more virulent virus from which it was derived.

Cold-passage hPIV-3 mutant strains derived from a wild-type hPIV-3 strain produced in cell culture (by 45 passages at low temperature; cold passages [cp]) were demonstrated to be stable and to grow well at the lower temperatures of the nasal passages, but not at the higher temperatures of the lower respiratory tract, and they were attenuated clinically.⁵⁵ The cp45 mutant strain was developed into a candidate hPIV-3 vaccine (hPIV-3 cp45) containing 20-point mutation with the desired characteristics of cold adaptation (ca), temperature sensitivity (ts), attenuation (att), and genetic stability.^{17,18,186,187} A second candidate hPIV-3 vaccine was developed from a closely related bovine hPIV-3 (bPIV-3). The protective surface glycoproteins, HN and F, of bPIV-3 and hPIV-3 share amino acid identities of 75% and 78%, respectively.²⁰² In contrast to hPIV, the bPIV-3 has restricted replication in humans and thus is attenuated. The hPIV-3 cp45 was evaluated in phase I and II clinical trials in adults, seropositive children, and seronegative infants as young as 1 month of age. In seropositive children and adults, the vaccines were not sufficiently immunogenic or protective.¹⁰⁸ In some trials of seronegative infants, the hPIV3 cp45 vaccine was too reactogenic and was associated with otitis media.^{55,108} Nonetheless, the vaccine readily produced infection and was immunogenic. Most toddlers and infants developed both humoral IgG and IgA anti-HN antibody responses, and the presence of maternal antibodies did not affect vaccine virus replication in the upper airway. Low titers of the attenuated virus were shed for 2 to 3 weeks after vaccination. The observation that a higher percentage of infants shed the virus after receiving the second dose 3 months after the first dose (62%), in contrast to those receiving the second dose 1 month after the first dose (24%), suggests a rapid waning of protective immunity.¹⁰⁸ In a subsequent trial of hPIV3 cp45 vaccine involving seronegative children 6 to 18 months old, the vaccine was found to be well tolerated, safe, and immunogenic.¹⁸ No significant difference was observed in frequency of side effects (including otitis media) between the vaccine and placebo. An attempt to combine the hPIV3 cp45 with live-attenuated RSV (cpts 248/404) found that replication of the attenuated RSV interfered with that of the attenuated hPIV-3.¹⁷

When a bovine PIV-3 (bPIV-3) vaccine was evaluated as a live-attenuated vaccine against hPIV-3, it was demonstrated to be safe and immunogenic against bPIV-3, but because of its antigenic differences from hPIV-3, it induced only a modest immune response against hPIV-3 in seronegative infants and children.^{75,112}

The use of reverse genetics is particularly applicable and beneficial in advancing the development of hPIV vaccines because the molecular virology of the PIVs has been relatively well deciphered.¹⁴⁹ This technology has allowed the development of such PIV candidate vaccines as those produced by recovering infectious hPIV and bPIV from cDNA. The systematic introduction of desired mutations into the viral genome with a well-defined passage history and with minimal risk for biologic contamination resulted in recombinant and chimeric vaccines with more precise and promising profiles. In a phase I trial with the recombinant virus (9r) hPIV-3 cp45 in seronegative infants 6 to less than 12 months of age, the vaccine appeared safe, well tolerated, and immunogenic.²⁰ After three vaccine doses administered at 2-month intervals, 76.9% of the infants had over a fourfold increase in hemagglutination inhibition antibody. Shedding of the vaccine virus was restricted in titer and in duration after the second and third doses, suggesting that an immune response was elicited. The cDNA-derived virus was also shown to be comparable to previously observed results with the biologically derived hPIV-3 cp45 vaccine.¹¹⁰ In an attempt to improve the immunogenicity, cDNA-derived chimeric human-bovine vaccines for PIV-3 were constructed by replacing the HN and F glycoproteins of bPIV-3 with those of hPIV-3, and substituting the N of hPIV-3 with that of bPIV-3.^{11,85,111} The chimeric vaccine was evaluated in adults and in hPIV-3 seropositive and seronegative children. Although the vaccine's

viral replication was highly restricted in both adults and seropositive children, it remained infectious in seronegative children, and antibody was produced after a single dose.¹¹³ However, the titer was lower than that observed among children with natural hPIV-3 infection, suggesting that a series of vaccinations, such as three injections 2 months apart, may improve the antibody response.

The need to protect against both hPIV and RSV early in life led to further modifications of the chimeric rB/hPIV3 that also allowed the expression of the G and/or F proteins of RSV.¹⁸³ The vaccine, when administered to seropositive children 1 to 9 years of age, appeared to be safe, but with restricted replication, and was minimally immunogenic.⁷³ Further investigation among seronegative infants (6 to 24 months of age) showed that seroconversion occurred for RSV in 67% and for hPIV-3 in 100% of the infants.²¹ Subunit vaccines containing HN and F proteins from hPIV-1 in hPIV-3 have not been encouraging, but the introduction of amino acid substitutions in various hPIV-1 genes was successful in creating an attenuated virus. A vaccine containing three attenuating elements that protected against hPIV-1 infection of both the upper and lower respiratory tract of African green monkeys¹⁴ has been tested in seronegative children, but immunogenicity was limited.¹³¹ Another Sendai-based hPIV1 vaccine has been only mildly immunogenic in 3- to 6-year-old children.¹ Although the need for a vaccine against hPIV-2 is less because of its lower prevalence and clinical significance in the first 6 months of life, several candidate hPIV-2 live-attenuated vaccines have been developed. Mutations in the L protein produced strains that were both temperature sensitive and attenuated. One of these mutant strains was found to be attenuated in an in vitro model of human ciliated airway epithelium and to provide significant protection against wild-type hPIV-2 challenge in African green monkeys.^{154,181}

Multiple other approaches to develop candidate hPIV vaccines through recombinant DNA technology are being explored and include chimeric PIV vaccines with heterologous paramyxoviruses and with viruses for which concurrent immunization would be desirable, such as RSV and influenza.^{13,133} Approaches combined with these creative techniques, such as novel adjuvants, immunomodulators, and vehicles for incorporation and administration of the vaccine, are evolving and may further enhance the protective immune response from PIV immunization.

Measles virus is a singular agent that causes a relatively distinct, exanthematous disease characterized by fever, cough, coryza, conjunctivitis, an erythematous maculopapular confluent rash, and a pathognomonic enanthem. Clinical measles is an epidemic disease, the incidence of which in the United States was reduced by the use of attenuated vaccines from 315 reported cases per 100,000 persons in the prevaccine era to fewer than 1 per 100,000 persons in 1992.⁸⁶ At present, measles no longer is an endemic disease in the United States.³⁸⁰ However, measles is still a major problem because of its worldwide prevalence, associated morbidity and mortality, and changing epidemiologic patterns in countries where vaccine use has been less than optimal.^{78,80,173,379}

HISTORY

In antiquity, measles and smallpox frequently were confused with each other, as well as with other exanthematous diseases.^{26,371} Major epidemics of both measles and smallpox occurred 1800 years ago in the Roman Empire and China.^{48,319} The first written record of measles generally is credited to Rhazes, a 10th century Persian physician.^{26,48,248,494,495} However, Rhazes quoted writers, including El Yahudi, a famous Hebrew physician, who lived 300 years earlier.⁴⁸ Rhazes identified measles as an entity distinct from smallpox.

During the Middle Ages in Europe, smallpox and measles continued to be confused. By the beginning of the 17th century, however, differentiation between the two diseases was relatively clear; death reports by London parish clerks in 1629 listed measles and smallpox separately.^{494,495} Repeated epidemics of measles were described in the English medical literature during the 17th and 18th centuries.²⁴⁸

The first account of measles in America was given by John Hall, who described epidemic disease in Boston in the fall of 1657.⁷⁰ The next epidemic in colonial America was reported in 1687. During the next 150 years, the interval between epidemics in Boston gradually decreased from 30 years to approximately 3 years. Epidemics during the 17th and 18th centuries involved persons of all ages, including neonates; coincident with a reduction in the interval between epidemics was a reduction in the age-specific incidence of measles. The reduction in time between epidemics can be attributed to the increased incidence of importation of measles that occurred as more and faster ships crossed the Atlantic and the population density in North America gradually increased. By the turn of the 19th century, both Boston and Philadelphia had sufficient populations for measles to propagate itself.

The first recognition of the contagiousness of measles is unclear. Shakespeare in *Coriolanus* was aware of its human-to-human transmission.^{494,495} Home,²¹⁹ in 1758, attempted to immunize against measles by applying a technique similar to the variolation used in smallpox.³⁹⁹ In 1911, Goldberger and Anderson¹⁸⁰ produced clinical measles in monkeys by injecting filtered material from acute cases of human disease.

The classic epidemiologic study of measles is the account described by Panum³⁸⁵ of the 1846 epidemic in the Faroe Islands. In this study, Panum confirmed that spread occurred solely through human-to-human contagion by the respiratory route, the incubation period was 14 days, and infection conveyed lifelong immunity.

The enanthem of measles, which is pathognomonic, was described carefully and presented by Koplik²⁶⁷⁻²⁶⁹ in 1896, 1898, and 1899.⁵⁵ However, Koplik spots clearly were recognized specifically about a century earlier by John Quier, a physician in Jamaica,^{55,178} as well as by Richard Hazeltine, a general practitioner in rural Maine.⁷⁰ Although Plotz⁴⁰⁰ reported cultivation of measles virus in 1938 and Rake and Shaffer⁴⁰⁵ noted similar findings in 1940, reliable tissue culture methods were not available until approximately 10 years later. In 1954, Enders and Peebles¹⁴² isolated

eight strains (from cases of measles) in human or simian renal cell cultures. These investigators also demonstrated the ability of convalescent-phase serum from a patient with measles to neutralize the viral cytopathogenic effect. The stage for vaccine development was set by recovery in tissue culture of the virus,¹⁴² adaptation of viral growth in chicken embryos,³²⁷ and, finally, cultivation of the virus in chicken embryo tissue culture cells.²⁵⁰

After extensive trials were conducted from 1958 through 1962, tissue culture-grown, inactivated ("killed"), and attenuated ("live") measles viral vaccines became available for general use in 1963.^{100,247,274,275} In the United States, a nationwide immunization effort instituted in 1965 and 1966 led to a dramatic reduction in the incidence of epidemic measles for several years. Epidemic measles recurred in 1971, 1977, and 1989, but at overall levels less than those in the prevaccine era.^{21,76,77,81,84,91,100,273} After initiation of the Childhood Immunization Initiative in 1977 and the Measles Elimination Program in 1978, the incidence of measles in the United States fell in 1981 to fewer than 1.5 cases per 100,000 population and remained at this low level until 1986.^{21,82,83,90} In 1990, the rate was 11.2 cases per 100,000 population, which was the highest it had been since 1977. After 1990, a substantial decline in the incidence of measles occurred in the United States, to a low of 86 confirmed cases in 2000.⁸⁵

PROPERTIES

Classification

Measles virus is a relatively large virus with helical capsid symmetry and an RNA genome.^{36,144,145,192,283} It is a singular virus, but phylogenetically it is most closely related to rinderpest virus, a pathogen of cattle. Genetic relationships suggest both viruses also share common ancestry with canine distemper.^{170,192} These agents, as well as peste des petits ruminants virus, dolphin morbillivirus, phocine distemper virus, and rinderpest virus, currently are included in the genus *Morbillivirus*; they are members of the Paramyxoviridae family.²⁸³ Formation of intranuclear inclusion bodies differentiates *Morbillivirus* species from other Paramyxoviridae.^{293,353} Measles virus differs from the other paramyxoviruses in that it does not possess specific neuraminidase activity and does not adsorb to neuraminic acid-containing cellular receptors.^{339,362,394,484} Measles virus hemagglutinates, whereas the other members of its genus do not.

Physical Properties

Measles virus is a roughly spherical but pleomorphic virus that ranges from 100 to 300 nm in diameter.^{36,144,145,192,353,371,484,485} The virion is composed of an outer lipoprotein envelope and an internal helical ribonucleocapsid. The virion contains eight proteins. The outer viral envelope is 10 to 22 nm thick, has short surface projections (peplomers), and contains three virus-coded proteins (F, H, and M).^{104,339,371}

Fusion (F) protein is a dumbbell-shaped transmembrane peplomer that causes membrane fusion of the virus and host cell and enables penetration of the virus into the host cell. The presence of both the H protein and the F protein is required for fusion. Syncytia formation requires basolateral targeting of F and H proteins, overcoming the epithelial barrier and increasing cell-to-cell spread.³³⁷

Hemagglutinin (H) protein is the receptor binding and hemagglutinating protein and is a conical transmembrane peplomer. In infection, H protein reacts with a host cellular receptor and triggers major conformational changes in F protein, ultimately resulting in insertion of the F protein into target membrane. More than one F trimer may interact with each H tetramer.³⁹⁸

FIG. 180.1 Electron micrograph of nucleocapsid fragments. (Courtesy Dr. John M. Adams.)

Matrix (M) protein is nonglycosylated and associated with the inner lipid bilayer of the envelope. It plays an important role in the maturation of the virus. In infected cells M protein interacts with the nucleocapsid and regulates MeV RNA synthesis and assembly.²³² Matrix protein interacts with the transmembrane proteins, modulates fusogenic capacity, and directs release of the virus from the apical surface, and F actin also interacts with these proteins, further modulating cell-to-cell fusion and virus assembly.^{49,352,478}

The nucleocapsid (N) protein (Fig. 180.1) wraps the 16-kilobase viral genomic RNA to form the helical ribonucleocapsid, a coiled rod with a diameter of 18 nm and a length of 1 μ m.^{366,369-371,482,484} N protein has a molecular weight of approximately 60 kDa. Approximately 5% of the nucleocapsid is RNA.^{204,471,483} The phosphoprotein (P) and the large polymerase (L) proteins are attached to the helical ribonucleocapsid. The other internal proteins of the virus are the C, and V proteins.

The phospho (P), C, and V proteins are all encoded by the P gene and alter innate response to infection. P protein forms the replicase complex along with L and N, and is a polymerase cofactor bonding to the nucleoside capsid and forming a dynamic protein interaction.⁵⁸ Both C and V proteins interact with cellular proteins and regulate response to infection. C regulates viral RNA synthesis, suppressing interferon (IFN) induction and cellular protein kinases and interfering with the innate immune response.³⁵⁴

The virus genome has a molecular weight of 4.5×10^6 daltons. It is a linear, single strand of RNA that contains approximately 15,900 nucleotides.

Cellular Receptors

Measles virus uses varying receptors for infection, depending on cell type, including CD46, signaling lymphocyte activation molecule (SLAM)/CD150, and nectin 4. CD46 appears to be the cellular receptor for attenuated measles vaccine strains but not wild-type viral strains.^{59,133,303,304,356,377} More recent data suggest that SLAM is the cellular receptor for wild-type virus.^{131,377,504} Nectin 4 allows measles virus entry in airway epithelial cells, sustains lateral spread, and is downregulated in infected cells.³⁴⁴ It appears that measles virus also uses other receptors for entry into central nervous system (CNS) cells and endothelial cells. Measles virus also interacts with cell surface molecules to enhance infection and to increase viral spread and pathogenicity, including toll-like receptor 2 (TLR2), intercellular adhesion molecule 3 (ICAM-3), and nonintegrin (DC-SIGN), and interacts with the cyclophilin ligand CD147/EMMPRIN.^{40,107,124,322,323}

Measles virus is labile.^{248,249,347} It is inactivated rapidly by heat, ultraviolet light, lipid solvents such as ether and chloroform, and extreme degrees of acidity and alkalinity (i.e., pH <5 and >10). Longevity is prolonged when protein is present in the virus-suspending medium and when the virus is lyophilized with a protein stabilizer. Protein specifically protects against the adverse effects of heat and light. Protein-stabilized measles virus can be stored at -70°C for 5 or more years

FIG. 180.2 Giant cell with approximately 20 nuclei showing measles virus cytopathogenic effect in monkey kidney tissue culture.

without significant loss of infectivity. At room temperature, a 60% loss in titer occurs in 3 to 5 days; at 56°C , the virus is inactivated within 30 minutes.^{42,43,259,347}

Antigenic Composition

Clinical and epidemiologic data and early laboratory study suggested antigenic homogeneity of all measles strains.²⁴⁹ More recent nucleotide sequence analysis identified distinct lineages among wild-type measles virus isolates, with most variation in H, N, and P genes.^{36,346,347,419,420,463} There are eight clades (A to H) that contain at least 24 genotypes. The global distribution of measles genotypes and measles molecular epidemiology has been extensively studied since the early 1990s by Rota and colleagues at the Centers for Disease Control and Prevention (CDC).⁴¹⁹⁻⁴²¹ Their work has been extremely useful for tracking global measles transmission patterns and for documenting the interruption of measles transmission in some countries.

The following properties have been associated with measles virus: a hemagglutinin (for simian cells), complement-fixing antigens, hemolytic activity, and a giant-cell-inducing factor.^{61,205,248,249,364,365,369,370,394,431,433} Human measles virus infection results in serum antibodies that are capable of neutralizing viral infectivity, fixing complement with viral antigen, and inhibiting viral hemagglutination and hemolysis.

Cross-seroreactivity occurs among members of the genus *Morbillivirus* but not with other members of the Paramyxoviridae family.^{45,65,229} Measles virus serum antibody in humans reacts with distemper virus, but canine serum after a case of distemper does not react with measles virus. A two-way cross between measles and rinderpest viruses has been demonstrated.

Tissue Culture Growth

Measles virus can be propagated in many different primary and cell line tissue cultures.^{44,231,288} However, for isolation of virus from patient specimens, primary human and monkey kidney cultures have been most successful over the years. Recently, isolation of wild-type strains of measles virus has been more successful in other cell lines, including an Epstein-Barr virus-transformed B-lymphocyte line, continuous monkey kidney cell lines (Vero) engineered to express measles virus receptor SLAM, or a human T-cell line from cord blood (COBL-a).^{262,270} In one study, an Epstein-Barr virus-transformed marmoset lymphocytic line (B95-8) was found to be superior to primary monkey kidney cell culture for isolation of virus from nasopharyngeal specimens.²⁶³

In tissue culture, measles virus has two distinct cytopathogenic effects. With initial isolation, syncytial formation occurs as a result of cell fusion, and the resulting giant cells may contain 10 to 50 or more nuclei (Fig. 180.2). On stained preparations, both the nuclei and cytoplasm contain eosinophilic inclusions. The second type of cytopathogenic effect is characterized by the alteration of single cells into spindle shapes or stellate forms. In general, tissue culture-adapted measles viral strains are more likely to cause this cytopathogenic effect than is giant-cell formation. In most cultures, both forms of cytopathogenic effect are

evident, and changes in medium composition render one or the other type predominant.

Infection in tissue culture is associated with an attachment-adsorption phase lasting approximately 1 hour and an eclipse period of 6 to 12 hours.^{313,339} Antigen first is noted in the perinuclear cytoplasm by 12 hours; by 24 hours, it is distributed throughout the cytoplasm. By 30 hours, most antigen is detected at the cell surface. In mature cultures, more cell-associated virus is present than is found free within the medium.

Animal Susceptibility

Humans are the natural hosts of measles virus, but, with human contact, monkeys also are infected easily.³²⁴ Laboratory strains of measles virus have been adapted to suckling mice and hamsters.^{60,64,230,479}

EPIDEMIOLOGY

Prevalence

The prevalence of measles throughout history has been affected markedly by population density and, since the 1960s, by the use of measles vaccine. Reported cases of measles in the United States from 1963 to 2015, analyzed by year, are presented in Fig. 180.3. After the universal use of measles vaccine began in 1965, the number of cases in the United States decreased to 22,231 in 1968.^{84,91} In 1971 to 1972 and 1976 to 1977, epidemics occurred; then, after a national commitment to measles immunization, the number of cases of measles fell to an all-time low of 1497 cases reported in 1983. Beginning in 1986, the number of measles cases again increased, with 27,786 cases reported in 1990.

From 1995 through 2015, there have been 3250 cases of measles reported in the United States.^{72,73,75} The mean number of reported cases during this period was 155 cases per year, with a range between 37 cases in 2004 and 667 cases in 2014 (see Fig. 180.3). Since 1998, the endemic transmission of measles in the United States has been eliminated.³⁸⁰ In 2005, 66 cases were reported in the United States, and 95% of these were linked to importations.⁸⁶ Half of all the cases in 2005 were traced to one unvaccinated traveler who was infected in Europe. All but two of the contact cases in this outbreak were unvaccinated because their parents had declined immunization. In 2011, there were 220 measles cases in the United States with 17 different outbreaks.^{79,91} Two hundred (90%) of these cases were associated with importations from other countries; this included United States residents returning

from abroad and foreign visitors. Most patients (86%) were unvaccinated or had unknown vaccination status.

Between January 4 and April 2, 2015, a total of 159 measles cases (155 US residents and four foreign visitors) from 18 states and the District of Columbia were reported to the CDC.^{71,74,512} At least 111 of these cases were directly related to exposures in December 2014 at Disney theme parks in Orange County, California. Of the 110 California patients linked to the Disneyland outbreak, 45% were unvaccinated, 5% had one dose of measles-containing vaccine, 7% had two or more doses of vaccine, 43% had unknown or undocumented vaccination status, and one patient was found to have measles immunoglobulin G (IgG) antibody indicating previous vaccination or infection.⁵¹² Of the unvaccinated, 12 were infants too young to be vaccinated and 28 were intentionally unvaccinated.

In the 20th century, before the widespread use of measles vaccine, between 200,000 and 600,000 cases of measles were reported annually in the United States.^{112,285} Careful survey suggested that in the past, reported cases accounted for only approximately 15% of the actual number of cases of measles.¹⁰⁰

In the prevaccine era in the United States and other concentrated populations throughout the world, measles epidemics occurred regularly. In the United States, urban-centered measles epidemics took place every 2 to 5 years, with each epidemic lasting 3 to 4 months.^{26,48,201,213,295,490,506} In general, the larger the community, the shorter the interval between epidemics. In the vaccine era, the epidemic pattern has been changed. As noted in Fig. 180.3, the total number of cases has been reduced, and the cycle between peaks has lengthened.

Age Incidence and Prevalence

In modern times in populous areas, measles has been a disease of children. The age-specific incidence in the United States for selected years is presented in Table 180.1. In the prevaccine era during the 20th century, the highest measles attack rate occurred in children aged 5 to 9 years.^{26,48,213,494,495} In the period 1960 to 1964, data from five reporting areas showed that more than half of all measles cases occurred in this age group.²⁰⁷ Before the present vaccine era, infections and epidemic loci centered in elementary schools. Younger children acquired measles as secondary cases from their older siblings who were attending school. In rural areas, the interval between measles epidemics tended to be greater; therefore, a broader spread in ages occurred in the percentage

FIG. 180.3 Reported measles cases by year in the United States (From Centers for Disease Control and Prevention. Summary of notifiable diseases—United States, 1998. *MMWR Morb Mortal Wkly Rep.* 1999;47:48.) Supplement to Centers for Disease Control and Prevention. Summary of Notifiable Diseases—United States, 2010. *MMWR Morb Mortal Wkly Rep.* 2012;59:96. Centers for Disease Control and Prevention. Measles Cases and Outbreaks. <http://www.cdc.gov/measles/cases-outbreaks.html>.

TABLE 180.1 Incidence and Percent Distribution of Reported Measles Cases by Age Group in Selected Years, United States

Age Group	1960–64 ^a			1974			1979			1991		
	Cases	%	Incidence ^b	Cases	%	Incidence ^b	Cases	%	Incidence ^b	Cases	%	Incidence ^b
<1–4	93,653	37.2	766	5899	26.7	36	2331	20.7	18.0	4756	49.3	24.7

^aData from four reporting areas: Washington, DC, New York City, Illinois (including Chicago), and Massachusetts.^{21,76,80,83,88,207}

^bIncidence, cases per 100,000 population, extrapolated from the age distribution of known cases.

of measles cases. In a nationwide serum survey of US military recruits in 1962, Black⁴⁴ found that 99% had measles antibody.

As noted in Table 180.1, the age-related incidence and percentage of measles cases by age group have changed markedly since 1964. In 1991, more than 40% of measles cases occurred in persons older than 10 years; in the period from 1960 to 1964, fewer than 10% of the patients were older than 10 years. Approximately one-third of the cases in 1991 were in adolescents and young adults. Evidence also indicates high primary measles attack rates in neonates to 4-year-old children in areas of suboptimal vaccine utilization.^{21,85,100,158,210} Because there has been no endemic sustained transmission of measles in the United States since 1998, cases today relate to international travel by US residents and importations.^{71,74,79,86,91,419,422} Of the 159 cases between January 4 and April 2, 2015 in the United States, 26 (16%) were younger than 12 months, 18 (12%) were aged 1 to 4 years, 27 (17%) were aged 5 to 19 years, 58 (36%) were aged 20 to 39 years, and 30 (19%) were 40 years or older.^{71,74} Measles in heavily populated but developing countries has its greatest incidence in children younger than 2 years.^{109,151,212,340,341,372}

Geographic Distribution

In the 20th century, measles occurred regularly throughout the world in all but the most remote areas.^{26,48} In island and other isolated populations, intervals between epidemics can be 10 years or more, and the occurrence of disease depends on its introduction from outside the area.

Seasonal Patterns

Epidemic measles is a winter-spring disease in temperate climates, with peak activity in the Northern Hemisphere occurring in March or April. In equatorial regions, epidemics of measles are less marked but tend to occur in the hot, dry seasons.^{26,340,342,414,460}

Host and Social Factors

No difference is found in the incidence of measles in males and females. One suggestion, however, is that complication rates are higher in boys or men than in girls or women. Tidstrom⁴⁶⁵ found that acute laryngitis occurred more than twice as frequently in male patients compared with female patients. In other studies, otitis media, pneumonia, and death occurred slightly more often in male patients.^{26,373} Miller,^{325,326} in a large survey in England in 1963, found no difference in the incidence of complications in male and female patients. Christensen and associates,¹⁰⁵ in studies of an epidemic in Greenland, noted a greater number of complications in female patients older than 15 years, attributable primarily to an increased incidence of pneumonia. In a review of 375 confirmed cases of subacute sclerosing panencephalitis (SSPE), the male-to-female ratio was 2.4:1.³³⁵ In one study,⁴⁸ antibody titers were slightly higher in women than in men. The studies by one of us (JDC) involving young adults in 1976 failed to reveal a similar sex-associated difference in antibody levels, however.⁴⁴⁶ Garenne and Aaby¹⁷² noted that a group of women had a higher postimmunization geometric mean antibody titer than did vaccinated men.

It had been observed in the 18th and 19th centuries that importation of measles into isolated populations resulted in devastating epidemics.^{319,440} The reason for this is not totally clear. However, McNeil²¹⁹

thought that, in populations where measles had been circulating for long periods of time, a pattern of mutual adaptation had occurred. This allowed both the virus and people to survive.

Although the severity of disease in certain populations in more recent times appears to suggest differences based on race, this difference may be the result of nutritional and other environmental factors. Deseda-Tous and associates¹²⁸ were unable to demonstrate any differences in measles antibody by human leukocyte antigen (HLA) or by ABO blood types. In a more recent study, the findings of Ovsyannikova and coworkers³⁸² suggested that HLA alleles relate to antibody responses after immunization. The following alleles were positively associated with hyperseropositivity: HLA-B*7, HLA-DQA1*0104, and HLA-DPA1*0202. In contrast, HLA-B*44, HLA-DRB1*01, HLA-DRB1*08, HLA-DQB1*0301, and HLA-DPD1*0401 alleles were negatively associated with hyper-seropositivity. In another study, the same group looked for associations between HLA homozygosity and measles antibody levels.⁴⁴⁷ They found a negative correlation between homozygosity (=1/loci) and antibody value. More recently, the same group of investigators found significant associations with class I HLA-B, as well as class II HLA-DPBI and HLA-DPA1 genes for measles vaccine-induced antibody values after the second vaccine dose.²³⁴ This group also noted associations between single nucleotide polymorphisms and haplotypes in cytokine and cytokine receptor genes and immunity after measles immunization.²⁰⁹

In the prevaccine era, the age of patients at the time of acquiring measles infection was related inversely to the number of siblings in the family.^{26,48,501} In general, measles occurred at an earlier age in city dwellers and those of lower socioeconomic classes than in rural families and well-educated, upper-income groups.

In the present era of antibiotics and other medical modalities, the greatest factors in measles-related morbidity and mortality are age and nutritional status. The mortality rates for measles are highest in children younger than 2 years and in adults.^{26,48} The severity of measles and rates of mortality correlate in general with the severity of malnutrition.^{44,337} However, extensive investigations by Aaby and others^{3,4,172} since the 1980s suggest that overcrowding and intensive exposure may be more important determinants of measles-related mortality than is nutritional status alone.

Studies of measles conducted early in the 20th century and in developing countries indicated that secondary cases in households were likely to be more severe than were primary cases.^{2-4,172} However, more recent studies in the United States found no difference in severity between primary and secondary cases in families.⁴⁵⁷

Spread of Infection

Measles is a highly contagious disease in nonimmune persons. It is spread from an infected ill person to a new host by the respiratory route.^{26,48,411,412,415} Although monkeys can acquire measles from humans, practically speaking, no animal reservoir exists.³²⁴ Available evidence suggests that infection is spread by persons ill with measles. Asymptomatic contagious carriers are unknown, and persons with acute asymptomatic infection probably are not contagious.²⁸⁹ Recent California data indicate that secondary vaccine failure cases are less contagious than cases with primary measles. (J.D. Cherry and J. Zippich, unpublished data).

However, a small number of secondary vaccine failure cases did transmit to contacts after prolonged contact. The period of greatest contagion occurs during the prodromal period.¹⁸⁰

Transmission of measles is thought to occur mainly by aerosolized droplets of respiratory secretions. Acquisition of infection by a new host is by the nose and possibly the conjunctivae.³⁸⁶ Infection can be initiated by small-droplet nuclei, which stay suspended in air for considerable periods of time, or by direct hits of large droplets at close range.^{50,409} Also possible is that spread involves close person-to-person contact in young children, with large virus-containing droplets of nasal secretions being picked up on the hands of the future host and then applied to the nose.

PATHOGENESIS AND PATHOLOGY

Viral Infection

The sequence of viral events in uncomplicated measles is presented in Table 180.2. Although much is known about measles virus infection in humans, considerable gaps exist regarding specific events. Experimental studies in other primates have been performed in an attempt to fill in the gaps and thereby provide a more complete picture.^{245,314,361,376,435,503}

The primary site of infection appears to be the respiratory epithelium of the nasopharynx. Measles vaccine virus instilled into the nose or by aerosol results in infection.^{46,47,272} Papp³⁸⁶ reported studies suggesting that infection resulted from conjunctival contact and proposed that this means was the primary portal of entry. However, experiments with vaccine virus generally have been unsuccessful when conjunctival inoculation has been performed.^{46,47} Initial infection of the respiratory epithelium appears to be minimal; a more important event is the early spread of virus to regional lymphatics. A presumption based on data derived from Fenner's ectromelia-mouse experimental model^{144,145} is that after such spread, primary viremia occurs, followed by extensive multiplication of virus in the reticuloendothelial system at both regional and distant sites. Multiplication of virus also continues at the site of initial infection.

During the fifth to seventh days of infection, extensive secondary viremia takes place and results in the establishment of generalized measles viral infection. The skin, conjunctivae, and respiratory tract are obvious sites of infection, but other organs may be involved as well. From the 11th to the 14th days, the viral content of the blood, respiratory tract, and other organs peaks and then rapidly diminishes over the ensuing 2- to 3-day period.

In immunologically compromised patients with defects in cell-mediated factors, measles virus is not cleared from the secondary infection

sites, and progressive, frequently fatal illnesses occur.^{8,141,329,331,343} During infection, measles virus replicates in endothelial cells, epithelial cells, and monocytes and macrophages.^{195,336}

Pathology

The characteristic pathologic feature of measles is the widespread distribution of multinucleated giant cells, which are the result of cell fusion.^{45,245,248,290,313,361,376,416,435,503} Two main types of giant cells occur in measles: (1) Warthin-Finkeldey cells, which are found in the reticuloendothelium; and (2) epithelial giant cells (Fig. 180.4), which occur principally in the respiratory epithelium but also on other epithelial surfaces.²⁹⁰

Warthin-Finkeldey giant cells are found throughout the reticuloendothelial system in the adenoids, tonsils, Peyer patches, appendix, lymph nodes, spleen, and thymus. They vary in size and contain as many as 100 or more nuclei. The cells contain both cytoplasmic and intranuclear eosinophilic inclusions, with cytoplasmic inclusions more common than intranuclear lesions. During the prodromal stage of measles, epithelial giant cells regularly are present on respiratory surfaces and frequently are sloughed free (see Fig. 180.4).

Measles Exanthem

Hematoxylin and eosin–stained sections of skin biopsy specimens have revealed typical epithelial syncytial giant cells with nuclear and cytoplasmic inclusions.^{257,456} The giant cells contain three to 26 nuclei. Other findings include the following: focal parakeratosis, dyskeratosis, spongiosis, and intracellular edema. The superficial blood vessels are dilated, with a sparse, surrounding lymphohistiocytic infiltrate.

Koplik Spots

Suringa and colleagues⁴⁵⁶ observed that the histopathologic features of Koplik spots were similar to those of the rash. These investigators noted more giant cells with more nuclei, a greater degree of edema, and a lessened inflammatory response in the enanthem biopsy sample, however.

Respiratory Tract

The extent of respiratory involvement in uncomplicated measles is not known. However, clinical symptoms and the extensive radiographic studies of Kohn and Koiransky²⁶⁵ suggested that pharyngitis, tracheitis, bronchitis, and pulmonary infiltration are the rule rather than the exception. Unfortunately, the human pathologic data available have been obtained mainly from complicated cases, so the findings cannot be considered representative.^{126,416} In a study in monkeys, Nii and colleagues³⁶¹ noted giant cells in the mucosal epithelium of the trachea,

TABLE 180.2 Sequence of Measles Virus Infection in Uncomplicated Primary Disease	
Day	Event
0	Measles virus in droplet nuclei or large droplet comes in contact with the epithelial surface of the nasopharynx or possibly the conjunctiva Infection of epithelial cells and virus multiplication
1–2	Extension of infection to regional lymphoid tissue
2–3	Primary viremia
3–5	Multiplication of measles virus in respiratory epithelium at the site of initial infection and in the reticuloendothelial system regionally and at distant sites
5–7	Secondary viremia
7–11	Establishment of infection in the skin and other viremic sites, including the respiratory tract
11–14	Virus in blood, respiratory tract, skin, and other organs
15–17	Viremia decreases and then ceases Viral content in organs rapidly diminishes

Data from references 190–192,195, 199, 245, 251, 257, 290, 361, 376, 393, 415, 424, 435, 503.

bronchi, and bronchioli. The lumina of these airways contained sloughed syncytial cells. Warthin-Finkeldey cells were found in the adjacent lymphatics.

In the lungs of experimentally infected monkeys, interstitial pneumonitis was observed with giant-cell formation.³⁶¹ Infiltration of neutrophils, eosinophils, and mononuclear cells also was noted.

Immunologic Events

After natural or attenuated measles virus infection develops, large numbers of specific and nonspecific immunologic responses occur. Many questions relating to immunity in measles remain unanswered, although a considerable body of knowledge has been gathered since the 1950s.

Antibody

After measles viral infection develops, an antibody response regularly occurs. Serum antibodies to the N, F, H, and M proteins of measles virus can be demonstrated by hemagglutination inhibition (HI), complement fixation (CF), neutralization, immune precipitation, hemolysin inhibition, enzyme-linked immunosorbent assay (ELISA), and fluorescent antibody (FA) methods.^{118,168,169,186,258,275,276,357,363,364,473} Antibody-dependent cellular cytotoxicity and antibody-dependent complement-mediated lysis also have been demonstrated.^{156,157,254} In natural infection, HI and neutralizing antibodies appear at approximately the 14th day, peak at around 4 to 6 weeks, and decrease approximately fourfold from the peak over the course of a year. Most naturally infected persons have demonstrable HI and neutralizing antibodies for life. Krugman^{273,274} noted an average 16-fold reduction in HI antibody titer 15 years after natural infection in a group of children who had no measles exposure during the observation period.

After measles vaccine has been administered, both HI and neutralizing antibodies are present by the 14th day.^{168,169,275,276} CF antibody appears slightly later than does HI antibody and in general does not persist as long as either HI or neutralizing antibody. Primary infection is characterized by the initial appearance of antibody in the IgM and IgG serum components.^{154,214,431-433,468} The IgM-specific response is short-lived, and rarely can measles antibody in this fraction be demonstrated more than 9 weeks after infection. IgA secretory antibody also occurs regularly after vaccine viral infection and after natural infection.^{34,163}

IgG antibody appearing after infection is primarily subclasses IgG1 and IgG4.³¹¹ Antibody detected by neutralization and by HI is mainly to H protein and correlates with clinical protection against illness.^{123,195,364} Antibody to N protein is the main antibody detected by CF.³⁶⁴ Antibody to F protein is demonstrated by inhibition of hemolysis of monkey erythrocytes by measles virus or by immunoprecipitation.^{363,365} Antibody to F protein may contribute to neutralization by disrupting the fusion of virus membrane with host cell membranes. Only small amounts of antibody to M protein are elicited after infection with wild virus or vaccine virus.¹⁸⁶

Specific Cell-Mediated Responses

Investigators recognized in the 1960s that patients with defective cellular resistance factors frequently died of progressive measles virus infections.³⁵¹ In the 1970s, techniques became available that demonstrated measles-specific lymphocyte sensitization.^{171,187,188,271,282,423} Graziano and colleagues¹⁸⁷ found that lymphocytes from persons who previously had measles had a blastogenic response in vitro when these cells were incubated with measles antigen. Labowskie and associates,²⁸² using an in vitro lymphocyte-mediated cytotoxicity assay, noted that lymphocytes from persons who previously had measles caused cell destruction in a tissue culture chronically infected with measles virus. Ruckdeschel and colleagues⁴²³ observed that two physicians without detectable measles antibody who had experienced repeated recent exposure to measles without developing illness had strong in vitro cellular responsiveness to measles virus. T cells are appreciated to be important both in B-cell antiviral antibody responses and as effector cells for the clearance of virus-infected cells from tissues.¹⁹⁵ Both helper (CD4⁺) and suppressor (CD8⁺) cells participate in the cellular response.⁴⁸¹ During infection, CD8⁺ T cells eliminate virus-infected cells by major histocompatibility complex (MHC) class I-restricted cytotoxic mechanisms.¹⁹⁵ CD4⁺ T

cells respond to measles virus infection by the secretion of cytokines. After initial exposure to virus occurs, CD4⁺ T cells mount a helper T-cell subtype 1 (Th1) response. Before the rash develops, levels of plasma IFN- γ are increased, and, with the rash, interleukin-2 (IL-2) appears. With clinical recovery, plasma levels of IL-4 increase (a Th2 response) and stay elevated for several weeks, whereas the initial Th1 response subsides.

On reexposure, Th1 and Th2 responses occur as indicated by the production of IFN- γ , IL-2, tumor necrosis factor- β (TNF- β), IL-4, IL-5, and IL-10. The Th1 cytokine response is important for macrophage activation (through the action of IFN- γ), lymphocyte proliferation (through IL-2), and MHC class II-restricted cytotoxicity (through TNF- β). The Th2 cytokine response is important for macrophage deactivation (through the action of IL-4 and IL-10) and B-cell help (through IL-4, IL-5, and IL-10). In studies in rhesus monkeys, researchers found that humoral immunity had only a limited role in the control of measles virus replication in primary infection.³⁹⁵

Ovsyannikova and colleagues³⁸³ found a predominant Th1 cytokine pattern after measles vaccine viral infection. This pattern occurred after both primary immunization and revaccination. In this study, no relationship was found between any specific cytokine level and serum measles antibody values. In another study, the same research group found a subset of vaccinees in whom the cytokine responses were skewed toward the Th2 type.¹³² These investigators suggested that this response in this subset may not be sufficient for long-term immunity.

Other Responses

Listed in Table 180.3 are nonspecific, immunologically related responses that can be demonstrated during natural or vaccine measles virus infection. Anderson and colleagues¹⁵ demonstrated a temporary defect in neutrophil motility during acute measles that resolved by the 11th day after the onset of rash. Leukopenia has been observed in natural measles³⁷ and after immunization.^{46,47} With immunization, the numbers of both neutrophils and lymphocytes are reduced; this reduction lasts approximately 1 week, with an onset occurring approximately 7 days after vaccination. Coovadia and colleagues^{114,115} showed that the numbers of T, B, and null cells in the lymphocyte population are reduced. With a reduction in the number of T lymphocytes, no change occurs in the ratio of helper and suppressor cytotoxic cell phenotypes.^{10,18,239}

Thrombocytopenia occasionally has been associated with natural measles²²⁵ and vaccination.^{11,492} Oski and Naiman³⁸¹ noted a mild reduction in the peripheral platelet count during routine measles immunization. Transitory complement defects vary in measles; Charlesworth and associates⁹⁴ found evidence of pathologic complement activation in 20 of 50 patents studied. Coovadia and colleagues¹¹⁵ noted slight but significant reductions in serum IgA levels and elevated IgM values in acute measles virus infections. These investigators found the IgG concentrations to be normal. Increased levels of serum or plasma IgE were noted in two studies.^{193,436} Delayed hypersensitivity responses in skin are suppressed in both natural and vaccine measles virus infection.^{148,448,449} Similarly, in vitro lymphocyte blastogenic responses to common antigens are suppressed.⁴⁹¹

Mechanisms in Recovery From Measles Viral Infection

Acute clinical measles is characterized by viral multiplication in many organs of the body and then rapid subsidence of the infection by the 17th day. As noted earlier, measles virus infection is associated with both serum and secretory antibody responses and specific cell-mediated responses that coincide with clinical recovery. All three factors would seem to be important in recovery from acute measles virus infection, but confusing information clouds the issue. For example, researchers have noted that children with simple agammaglobulinemia in whom measurable measles antibodies do not develop after measles virus infection recover from the disease normally.¹⁸² This finding suggests that development of measles antibody is not important for recovery from acute infection. However, by using a sensitive plaque-reduction measles neutralizing antibody technique, Black^{42,43} found small amounts of antibody in the sera of three agammaglobulinemic patients.

In contrast to antibody data, data on patients with defects in the cell-mediated immune system show that they clearly do poorly with

TABLE 180.3 Nonspecific, Immunologically Related Responses During Measles Virus Infection

Category	Findings	Reference
Leukocytes	Defective neutrophil motility	15
	Leukopenia (both lymphocytes and neutrophils)	37, 48
	Decreased T, B, and null lymphocytes	10, 18, 114, 115, 239
	Decreased natural killer cell activity	198
	Decreased helper T cells	119, 255
	Prolonged suppression of interleukin-12 production	20
	Prolonged depression of virus-specific interferon- α production	355
Interferon- α	Elevated plasma levels	196, 197
Neopterin	Elevated plasma levels	196, 197
Interleukin-2 receptor (soluble)	Elevated plasma levels	196, 197
Platelets	Reduction in peripheral count	381
Complement	Frequent pathologic activation of the complement system; reduction of C1q, C4, C3, and C5	94
Serum immunoglobulins	IgA reduced and IgE and IgM elevated	115, 193, 436
In vitro lymphocyte response to phytohemagglutinin	Suppressed in presence of autologous serum; normal in presence of calf serum	491
In vitro lymphocyte response to <i>Candida</i>	Suppressed	491
Cutaneous delayed hypersensitivity	Depressed	148
C-reactive protein	Elevated at onset of rash	194
Circulating immune complexes	Noted in 25% of patients 7 to 13 days after rash onset	511

measles virus infection and frequently succumb to progressive infection despite the administration of large doses of measles antibody-containing immunoglobulin. T cells (both CD4⁺ and CD8⁺) clear virus-infected cells from tissues by cytotoxicity. IFN- α , which is released by a variety of cells, including T cells, inhibits the spread of virus infection.

In studies in a transgenic mouse model system, Tishon and associates⁴⁶⁷ showed that CD4, CD8, or B cells alone controlled measles virus infection. However, combinations of CD4 T cells and B cells or CD4 and CD8 T cells were essential in clearing infection. In contrast, the combination of CD5 T cells and B cells was ineffective.

Mechanisms in Prevention of Repeat Illness in Persons Previously Infected With Measles Virus

In contrast to mechanisms of recovery in acute measles, the role of serum antibody in protection against recurrent disease is solid. Before the present vaccine era, researchers repeatedly demonstrated that the administration of measles antibody-containing immunoglobulin could prevent clinical measles.^{235,453} Similarly, infants with transplacentally acquired measles antibody are immune.^{275,276} Whether other factors also are important in protection against reinfection is not clear. Often cited is that patients with agammaglobulinemia do not have repeated measles virus infections, so other factors must be involved.¹⁸²

Of interest is that patients have been described in whom antibody did not prevent acquisition of atypical measles after immunization with killed measles vaccine.²⁹² The data of Krause and associates²⁷¹ suggested that persons in whom the capacity for exaggerated measles-specific lymphocyte activity (when tested with formalin inactivated measles virus) persists (some previous killed vaccine recipients) may be subject to illness despite the presence of antibody. However, the antibody produced after receipt of killed measles vaccine was incomplete; it lacked specific antibody to F protein.^{42,43,104} Black noted one child with a low measles neutralizing antibody titer, presumably from natural measles virus infection, in whom measles later developed. Chen and coworkers⁹⁶ found that some students with measurable but low neutralizing antibody titers were not protected from clinical measles on exposure.

CLINICAL MANIFESTATIONS

Before the present vaccine era, measles was an inevitable disease of childhood that was recognized readily by parents and other laypersons, as well as by physicians. Despite the occasional confusion with other exanthematous diseases,⁹⁸ the epidemic character of measles usually resulted in an accurate diagnosis. Currently in North America, few of

the new generation of parents, physicians, and other medical personnel have seen measles; therefore, the illness can be misdiagnosed.

Typical Illness

Incubation Period

The incubation period^{26,99,100,248,278,415,452} of measles is approximately 10 days (range, 8–12 days). Although extensive virologic and immunologic events occur during this period, the individual has virtually no outward sign of illness. Goodall¹⁸³ suggested (and Partington and Quinton³⁸⁸ presented supporting data) that some patients have mild transient respiratory symptoms and fever shortly after initial acquisition of the virus.

Prodromal Period

The prodrome of measles lasts approximately 3 days (range, 2–4 days). Initial symptoms are respiratory and suggest the possibility of a cold, except that fever is an early sign. In fact, in situations of close observation, slight temperature elevation has occurred and then subsided for a day or so before the appearance of typical respiratory symptoms.⁴⁵²

The onset of clinical measles is characterized by general malaise, fever, coryza, conjunctivitis, and cough. These symptoms worsen during a 2- to 4-day period. Early in the prodromal phase, a transitory rash occasionally has been observed. It has been urticarial or macular, has occurred with the initial onset of fever, and has disappeared before onset of the typical exanthem.

During the prodromal period, the temperature increases gradually to a value of $39.5^{\circ} \pm 1.1^{\circ}\text{C}$ ($103^{\circ} \pm 2^{\circ}\text{F}$) over the course of a 4-day period. The nasal symptoms resemble those of other viral respiratory tract infections and are similar to those of the common cold or acute nasopharyngitis. Sneezing, rhinitis, and congestion are common symptoms. The degree of prodromal conjunctivitis varies considerably. Initially, the conjunctival infection is divided by a transverse marginal line across the lower lids.⁴⁵¹ The conjunctivitis is associated with considerable lacrimation, and older patients in particular are bothered by photophobia, which frequently is severe. Slit-lamp examination reveals both corneal and conjunctival lesions.^{25,150}

The cough in prodromal measles frequently is troublesome. It worsens throughout the period and often has a brassy quality suggesting laryngeal and tracheal involvement. On day 10 ± 1 , Koplik spots, the pathognomonic enanthem of measles, first appear (Fig. 180.5). Koplik²⁶⁷⁻²⁶⁹ originally described the lesions as bluish-white specks on a bright-red mucosal surface. In the experience of one of us (J.D.C.), the lesions always have appeared white, and a blue component was not observed. Koplik spots

FIG. 180.5 Koplik spots with involvement of the buccal and lower labial mucosa.

first arise on the buccal mucosa opposite the lower molars but usually spread quickly to involve most of the buccal and lower labial mucosa. The lesions are approximately 1 mm at first but occasionally seem to coalesce into larger lesions. Initially, only a few lesions appear, but within 12 hours the number usually is uncountable. Of equal importance in establishing the diagnosis is the appearance of the background mucosal surface, which is always bright red and granular. Frequently, 1-mm lesions (Fordyce aphthae), which commonly occur normally in adolescents and adults, are confused with Koplik spots.³⁷ These lesions, however, can be differentiated easily because they appear on a normal pale mucosal surface rather than the bright-red background of measles.

During the prodromal period, erythematous maculopapular lesions also are observed occasionally on the palate. At the end of the prodromal period, the posterior pharyngeal wall usually is erythematous, and the patient may complain of a sore throat.

Exanthem Period

In typical measles, the exanthem appears on approximately the 14th day after exposure. The exanthem occurs at approximately the peak of the respiratory symptoms and when the temperature usually is approximately 39.5°C (103°F). At this time, the manifestation of Koplik spots has peaked, and during the next 3 days the spots disappear. However, after the specific white spots have disappeared, the red, sandpapery mucosal background remains for a day or so.

The measles exanthem first appears behind the ears and on the forehead at the hairline. Spread of the rash is centrifugal from the head to the feet. By the third day, the rash has involved the face, neck, trunk, upper extremities, buttocks, and lower extremities sequentially. The rash initially is erythematous and maculopapular but progresses to confluence in the same centrifugal manner as it is spread. Confluence always is more prominent on the face; frequently, the lesions on the lower extremities remain discrete. At the height of the rash, the appearance suggests microvesicles on top of a generalized erythematous confluent base (Fig. 180.6).

The exanthem begins to clear on the third to fourth day, again following the centrifugal course of progression. During the initial stages of the rash, its color is red and it readily blanches on pressure. As the rash fades, it takes on a coppery appearance, after which a brownish discoloration is seen that does not clear with pressure. With healing, a fine desquamation frequently occurs in confluent areas with brownish discoloration. The duration of the exanthem usually is 6 to 7 days.

During the exanthem period, the fever generally peaks on approximately the second or third day of the rash and then falls by lysis during a 24-hour period. Fever that persists after the third or fourth day of exanthem usually is an indication of a complication. Conjunctivitis and nasal symptoms generally subside at about the time of defervescence. Continued nasal discharge, whether purulent or not, suggests bacterial secondary infection. With the appearance of the rash, the cough loosens up, and in older persons it frequently becomes productive. The cough may persist for 10 days or more.

FIG. 180.6 Measles exanthem. Note the generalized erythematous confluent base supporting small papular and microvesicular lesions.

Pharyngitis is a common development during the exanthem period, as is enlargement of cervical lymph nodes. Generalized lymphadenopathy with suboccipital and postauricular involvement is not an uncommon finding, nor is splenomegaly. Young children occasionally have diarrhea, vomiting, laryngitis, and croup. Abdominal pain also can be troublesome.

Laboratory Findings

Laboratory studies rarely are indicated for acute uncomplicated typical measles because the diagnosis can be established on a clinical and epidemiologic basis, and the results of studies rarely affect management of the patient. During the periods of prodrome and rash, the total leukocyte count is low. Numbers of neutrophils and lymphocytes are reduced, but the most marked reduction, when absolute counts are considered, is in the number of lymphocytes.³⁷ As noted in Table 180.3, there may be a reduction in the platelet count and an elevation in C-reactive protein value, and skin test (such as the tuberculin) reactions may be suppressed.

Modified Illness

Modified measles* is an infection that occurs in a partially immune person. It is characterized by a generally mild illness that usually follows the regular sequence of events in measles. The prodromal period is shorter; cough, coryza, and fever are minimal. Koplik spots are few and transient, and they frequently do not occur. The exanthem follows the progression pattern of regular measles, but confluence of the lesions does not occur. Because serologic studies reveal some children with measles antibody who have never had clinical disease suggestive of measles, some modified infections probably occur without exanthem and perhaps without overt symptoms at all.^{42,43,276,277}

Modified measles develops under a variety of circumstances, the most important of which historically was the result of intentional alteration of disease by the administration of immune serum globulin to an exposed susceptible child. Naturally occurring modified measles is seen occasionally in infants younger than 9 months because of the presence of transplacentally acquired maternal measles antibody.

Today the main cause of modified measles is secondary vaccine failure. In this instance, patients have had modified illness but demonstrated a secondary measles serum antibody response (only IgG antibody).^{100,103,444} With increasing time from immunization, this response will occur more frequently.^{24,96,127,139}

Recurrent measles also rarely results in modified illness. The frequency of recurrent measles is unknown. In general, most authorities have discounted the existence of recurrent measles and suggested that the recorded experiences were the result of confusion with infection by other exanthem-producing agents.^{98,274,275} However, Cherry and colleagues,¹⁰⁰ Schaffner and associates,⁴²⁹ and Schluederberg^{432,433} have

*References 26, 30, 96, 100, 103, 139, 168, 169, 216, 235, 278, 390, 410, 429.

described children with modified illnesses, secondary immunologic responses, and well-documented instances of previous cases of measles.

Atypical Measles

Atypical measles is a clearly defined clinical syndrome that occurs in some previously immunized persons after they have been exposed to natural measles. Most cases have occurred in persons who initially received inactivated (killed) measles viral vaccines, but some cases also have been noted in children who received only live measles vaccines.^{101,292,358}

Historical Aspects

The initial studies with inactivated measles vaccines in the early 1960s demonstrated that multiple doses were necessary to stimulate an antibody response and that measurable serum antibody levels were short-lived.^{168,169,200,246,275,276,496} In the initial trials, it soon became apparent that some study participants who had received killed vaccine were still susceptible to measles. On being exposed to natural measles, some children developed typical measles, and others developed a mild, modified illness.^{168,169} As a result, regimens were developed in which children were immunized with two or three doses of killed vaccine at monthly intervals, followed in a month or more by a single dose of Edmonston B live measles vaccine (KKL or KKKL). Studies at the time demonstrated that good antibody levels were achieved after administration of both regimens. After measles vaccine was licensed in 1963, killed-live measles vaccine regimens enjoyed modest popularity in the United States (as well as in other countries) because live Edmonston B strain vaccine frequently was associated with alarming febrile responses and occasional febrile convulsions.

In 1965, Rauh and Schmidt⁴⁰⁷ reported an unusual illness after exposure to natural measles in some children who had received killed vaccine 2 years previously. The significance of their findings became more apparent during the following 2 years when Fulginiti and colleagues¹⁶⁶ and Nader and coworkers³⁴⁹ noted many instances of “atypical measles” in previous recipients of KKL and KKL vaccination regimens. In these two instances, original immunization had taken place 4 to 6 years before the occurrence of atypical illness.

In 1968, killed measles vaccine was taken off the market in the United States after the distribution of approximately 1.8 million doses in the period from 1963 to 1968.³⁷⁸ During the 12-year period from 1968 to 1980, atypical measles was reported frequently.* We are unaware of reports since 1980 of further cases of atypical measles. However, one of us (J.D.C.) observed one 26-year-old physician and a 28-year-old nurse with the syndrome in the 1980s. Sporadic cases in adults may still be occurring but are misdiagnosed because physicians caring for adults are unaware of the syndrome; therefore, the history of killed measles vaccine is not uncovered and specific antibody studies are not performed.

In 1971, during study of an extensive measles epidemic, Cherry and colleagues¹⁰¹ observed six children who had relatively mild, atypical measles-like illnesses but had received only live measles vaccine. Linnemann and colleagues²⁹² similarly noted two children with atypical measles-like illnesses who had received only live measles vaccine. Nichols³⁵⁸ and St. Geme and associates¹⁷⁴ also have reported bizarre measles illnesses in patients who formerly received live vaccine.

Clinical Characteristics

Atypical measles was a common illness from 1967 to 1978. Because killed measles vaccines have not been available in the United States since 1968, two obvious facts need to be mentioned: with each passing year, potential patients and actual patients with atypical measles will be 1 year older and also 1 year farther from the time of receiving the primary killed measles vaccine immunization series. Both these aspects raise concern about whether the clinical manifestations of the syndrome will remain the same today as when the illness first was described. It was the opinion of one of us (JDC) in 1981 that the syndrome had

changed slightly but still was recognizable from original descriptions of the illness.⁹⁹

The incubation period of atypical measles is similar to that of typical measles—between 7 and 14 days in duration. The prodromal period is characterized by the sudden onset of high fever (39.5°C–40.6°C [103°F–105°F]) and usually headache. Abdominal pain and myalgia also are common complaints. Dry, nonproductive cough occurs in most patients, and vomiting is noted in approximately one-third of those afflicted. Pleuritic chest pain and weakness also are common complaints. Although few reports to the contrary exist, Koplik spots appear to be rare in atypical measles.

Two to 3 days after onset of the illness, the rash appears. It is unique in that it first develops on the distal ends of the extremities and progresses in a cephalad direction. Usually, the rash initially is erythematous and maculopapular. One of us (J.D.C.) has been impressed by a slight yellowish hue of the exanthem when compared with that of typical measles. The rash is particularly prominent on the wrists and ankles; it involves the palms and soles. Spread of the rash varies considerably. In some patients, only the wrists and ankles are involved, whereas in others, the entire extremities and the lower part of the trunk are affected. In a peculiar fashion, the rash frequently seems to end its cephalad progression in a line at the level of the nipples. Occasionally, a few erythematous, maculopapular but discrete lesions are found on the face. In some cases, the rash becomes vesicular, with the lesions 2 to 3 mm in diameter; they do not proceed to scab formation as in varicella, but occasionally pruritus is a problem, and excoriation occurs from scratching. The exanthem often has a petechial or purpuric component, and urticaria also occurs frequently. Edema of the extremities has been a common finding.

Although coryza has been noted in a few reports, it is not a prominent feature, nor is conjunctivitis. Respiratory distress with dyspnea and rales occurs commonly, and radiographic examination reveals pulmonary involvement in virtually all cases. Most patients have hilar adenopathy and pneumonia. Pleural effusion also occurs frequently. The pneumonia in atypical measles usually is lobular or segmental, and the lesions often appear nodular (Fig. 180.7). Although initial descriptions of the syndrome suggested an illness of approximately 1 week's duration, later observations indicated illnesses of 2 weeks or more. In one case, fatigue and other symptoms persisted for more than 1.5 years.

In the original description by Rauh and Schmidt,⁴⁰⁷ one patient had an exanthem that was biphasic; initially, a transitory rash suggested modified measles. Two weeks later, the more characteristic atypical exanthem developed. The same observers also noted a second case with a biphasic exanthem in which the first lesions were vesicular and occurred when the child had little fever. The second exanthem was maculopapular

FIG. 180.7 Nodular pulmonary infiltrates in a child with atypical measles.

*References 17, 57, 95, 101, 167, 179, 203, 217, 223, 286, 317, 328, 358, 360, 367, 368, 488, 489, 507–509.

and associated with a febrile response. Zahradnik and colleagues⁵⁰⁹ also noted a similar sequence in two young adults. Two patients who had received killed measles vaccine in the past had radiographic evidence of characteristic pulmonary findings, but the typical exanthem did not develop.^{367,368,507,508}

Other findings in atypical measles include marked hepatosplenomegaly,⁴⁰⁷ marked hyperesthesia,³⁴⁹ weakness,²⁸⁶ and numbness and paresthesia.³¹⁷ Personal observations by one of us (J.D.C.) of cases in adolescents and young adults suggest that the exanthem is less prominent than in past cases, and the fever and overall morbidity are of greater duration. Follow-up radiographic studies demonstrated the persistence of nodular pulmonary lesions for longer than 1 year in several patients and up to 6 years in one patient.^{286,328,507,508}

Measles antibody studies in atypical measles are remarkably diagnostic. If an initial serum sample is obtained before or at onset of the exanthem, CF and HI titers usually are less than 1:5. By the 10th day of illness, both titers are elevated markedly, and most are 1:1280 or greater. In contrast, in typical natural measles at the 10th day of illness, the titer rarely is greater than 1:160.

Measles virus was not recovered from any patients with atypical measles, but only a few adequately performed studies were performed. The epidemiologic data currently available suggest that patients with atypical measles are not contagious. Other laboratory studies are not particularly useful in atypical measles. The erythrocyte sedimentation rate is elevated. When serial blood cell counts have been performed, slight early leukopenia and late eosinophilia have been noted.¹⁶⁶

The pathogenesis of atypical measles was studied by several investigators, and several possible mechanisms were suggested,⁴⁰¹ including a generalized Arthus reaction, induction of abnormal measles virus-specific, delayed-type hypersensitivity, and an imbalance in antibody responses to H and F proteins caused by denaturation of F protein during formalin inactivation of the vaccine virus. In a study in monkeys, Polack and associates⁴⁰¹ found that atypical measles resulted from previous priming for a nonproductive type 2 CD4⁺ T-cell response and not from the lack of functional antibody against F protein. In revaccination studies performed by Cherry and colleagues in the 1970s, it was found that vaccinees with severe local reactions had marked lymphocyte reactivity to formalin inactivated measles virus and absent or minimal HI antibody.²⁷¹

Unusual Manifestations and Complications of Measles

In addition to typical measles, modified measles, and atypical measles, many other clinical manifestations and complications occur at a broad range of frequency. By definition, unusual manifestations are a direct result of the primary viral infection, whereas complications are a result of damage by a secondary infection with another microorganism. In many instances, determining whether a particular manifestation is just viral or involves a second agent is difficult. Combinations of infections are common occurrences.

In general, complications resulting from secondary infection are not as common today as they were before the antibiotic era; however, no evidence suggests that unusual manifestations of illness occur less frequently today than formerly. To demonstrate the magnitude of the problem today, the findings in a 1970 to 1971 hospital survey in St. Louis are revealing.^{100,102} In this period, an extensive epidemic occurred, with 10,000 cases of measles. In eight area hospitals, 130 children (1.3%) were admitted; 66 cases of pneumonia and six fatalities occurred, and six children had encephalitis.

The records of measles patients in three hospitals were reviewed carefully. Of this group of 71 patients, 53 had pneumonia; 37 of the patients with pneumonia had either previous cardiorespiratory or other chronic systemic disorders. Two children had mediastinal and subcutaneous emphysema. All six deaths were caused by fulminant pneumonia. Of the six children with encephalitis, severe residual neurologic damage developed in three. One child had acute measles appendicitis with perforation and peritonitis, and another patient had mesenteric lymphadenitis.

Pneumonia

Pulmonary involvement in measles, as a result of the viral infection, is probably the rule rather than the exception. Kohn and Koiransky²⁶⁵

performed careful radiographic studies in 130 children with measles and noted that 55% had pneumonic infiltration and 74% had hilar adenopathy. In most instances, the pneumonia was observed early in the course of the illness, a finding that suggested primary viral involvement rather than secondary bacterial infection. In the 1970 to 1971 St. Louis measles epidemic, approximately one in every 150 patients with measles was hospitalized because of pneumonia.

Pneumonia in measles has varied radiographic manifestations.^{6,102,189,265,294,302,310,373,458} Clearly, viral pneumonia is characterized by bilateral hyperinflation with diffuse fluffy infiltrates that are more confluent at the hilum. Unilateral, segmental, and lobar pneumonias also are observed. Gremillion and Crawford¹⁸⁹ reviewed 106 cases of pneumonia that occurred in 3220 Air Force recruits with measles between 1976 and 1979. Illnesses were severe, but no deaths occurred. Bacterial superinfection was documented in 30.3% of the cases; bronchospasm occurred in 17% of the recruits with pneumonia. In one study, seven children with massive and bilateral lung consolidation had clinical findings consistent with adult respiratory distress syndrome.⁶

Clinically, young infants have a picture of bronchiolitis with expiratory distress. In severe cases at all ages, a marked ventilation-perfusion deficit is noted.^{294,389} Patients with defects in the cell-mediated immune system are particularly prone to progressive fatal bilateral infection.^{141,264,329,331,442,445}

Secondary bacterial pneumonia is the result of common respiratory pathogens, particularly *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Streptococcus pyogenes*, and *Staphylococcus aureus*. Coinfection with other viruses also was noted in an extensive study of measles-associated pneumonia in the Philippines.⁴⁰⁴ In this study, parainfluenza virus and adenoviruses were isolated most frequently.

Other Respiratory Manifestations

Otitis media is the most common complication and is age related. In the immediate prevaccine era in the United States, otitis media developed in 5% to 15% of patients with measles. It now is less of a problem because of the change in the age-related incidence of measles. The bacterial pathogens in otitis media associated with measles are similar to those in otitis media in children without measles. Mastoiditis was a common complication of measles in the era before antibiotics, but fortunately today it is rare.

Laryngitis and mild laryngotracheitis occur commonly. Occasionally, frank, severe laryngotracheobronchitis occurs and may require tracheotomy.^{417,418} Measles-associated bacterial tracheitis is not an uncommon finding.¹¹⁰ Secondary bacterial infection of the cervical lymph nodes and secondary bacterial pharyngitis also are rather frequent complications of measles. Field¹⁴⁶ attributed 3.2% of cases of childhood bronchiectasis to former infection with measles virus.¹⁴⁶ Measles also has a deleterious effect on the course of tuberculosis.^{448,449}

Cardiac Manifestations

Myocarditis and pericarditis occasionally occur in cases of measles.^{126,147} Nonspecific, transient electrocardiographic abnormalities were noted in more than half of 71 children with measles in one study.^{417,418} In another study, 19% of patients had transient but clear-cut abnormalities, including T-wave changes, atrioventricular conduction defects, and premature auricular contractions.¹⁸¹ Although cardiac involvement appears to occur frequently in measles, clinical consequences from such involvement are rare developments.

Neurologic Manifestations

Neurologic involvement is not an uncommon finding in patients with measles.* Gibbs and associates noted that 51% of 680 patients with measles who had no clinical evidence of encephalitis had abnormal electroencephalographic results during acute or immediate postacute illness. Although the incidence varies, clinically evident encephalitis occurs in 0.5 to 1 of every 1000 measles cases.^{25,78,80,100,140,247} From 1962 to 1979, the average measles encephalitis-to-case ratio was 0.73:1000.^{78,80} Both mortality and the incidence of sequelae have varied in the reports available. LaBocchetta and Tornay²⁸¹ noted a mortality rate of 32% in

*References 5, 26, 38, 140, 143, 177, 185, 281, 297, 316, 384, 402, 470, 510.

50 patients in a group seen before 1947 and a rate of 11.5% in a group seen between 1947 and 1957. Ziegler⁵¹⁰ reported only two deaths in a group of 38 cases. Long-term morbidity data also vary considerably. In general, between 20% and 40% of patients who recover from measles encephalitis have manifestations of brain damage. Douglas¹³⁴ could find no evidence of later subnormal school performance in a group of children who had uncomplicated measles.

Symptoms of encephalitis usually develop during the period of measles exanthem and within 8 days of the onset of illness.^{5,281,416} Occasionally, the onset of CNS signs and symptoms occurs during the prodromal period. LaBocchetta and Tornay²⁸¹ noted the following frequencies of signs and symptoms at the onset of measles encephalitis: convulsions, 56%; lethargy, 46%; coma, 28%; and irritability, 26%. Patients with encephalitis frequently have multiple findings: headache, abnormalities in respiratory rate and rhythm, twitching and other involuntary movements, and disorientation. Cerebellar ataxia, myelitis, retrobulbar neuritis, transient mental disorders, and hemiplegia are findings noted during the subacute stages of illness. Long-term sequelae include various degrees of retardation and selective brain damage, recurrent seizures, deafness, and hemiplegia and paraplegia. An 8-year-old girl developed pseudotumor cerebri 3 weeks after having a case of measles.⁴⁶¹

Examination of cerebrospinal fluid (CSF) in measles encephalitis usually reveals mild pleocytosis with a predominance of mononuclear cells, mildly elevated protein values, and a normal glucose level.^{281,316,374,470} In one study, in 15% of the cases, CSF pleocytosis was not found.²⁸¹

Considerable controversy relates to the mechanisms in measles encephalitis.* Some investigators failed to isolate measles virus or to demonstrate measles virus RNA or other viral antigens in the brain of affected patients.^{175,243,252,336} These findings led to the widespread consensus that the illness is autoimmune (acute disseminated encephalomyelitis [ADEM]) and that viral invasion of the CSF is unnecessary. However, other investigators have recovered measles virus from the CSF and brain of affected patients, a finding indicating that the virus is involved directly in the process.^{143,153,316,464} In the hamster model of measles virus encephalitis, virus can be cultured directly from the brain.³⁸⁷

Other Manifestations

Measles has been associated with many other manifestations and complications. Of historical interest was the occurrence of a severe, often fatal, form of measles called *black measles* that was characterized by a confluent hemorrhagic skin eruption.²⁷⁸ Patients with this illness had signs of both encephalitis or encephalopathy and pneumonia. Extensive bleeding from the mouth, nose, and bowel frequently occurred. Severe hemorrhagic measles rarely is seen today, and little is known about its pathogenesis. Disseminated intravascular coagulation would appear to play a role.

Another complication of measles involving bleeding is thrombocytopenic purpura.^{6,225} It is a postinfectious illness and different from hemorrhagic measles. Although bleeding is extensive on occasion, the ultimate prognosis usually is good. Stevens-Johnson syndrome has been noted occasionally in measles.³⁰⁵ Other manifestations include pneumomediastinum, subcutaneous emphysema, hepatitis, appendicitis, ileocolitis, mesenteric lymphadenitis, cervicitis, acute glomerulonephritis, corneal ulceration, and gangrene of the extremities.^{159,215,247,253,278,291,318,338,359,441,466,502}

Measles in pregnancy results in significant maternal and fetal morbidity and mortality.^{23,138,238,343,450} Jespersen and associates²³⁸ retrospectively reviewed 10 epidemics of measles in Greenland; these investigators obtained adequate data on 327 women infected during pregnancy, and they also were able to examine 252 of the offspring. Thirty-two percent of women infected during the first trimester had spontaneous abortions, and 9% of these pregnancies that continued to term resulted in stillbirths. Congenital malformations occurred in 8 of 300 live-born infants.²³⁸ Pneumonia is a frequent maternal complication of measles during pregnancy.^{23,138}

Clinical measles shortly before birth in the mother-to-be has resulted in congenital infection and illness in the neonate.¹⁷⁶ Congenital measles is often severe, with death occurring in approximately 32%.

Subacute Sclerosing Panencephalitis

SSPE is an uncommon, slowly progressive disease of the CNS, with an almost invariably fatal outcome. The disease was recognized by a number of investigators early in the 20th century.^{53,120,425} Several early accounts, especially those published by Dawson in 1933,¹²⁰ suggested a viral origin of this disease; however, not until the mid-1960s was measles virus clearly demonstrated to be the causative agent.^{42,43,94,111,221,391,463} Today, SSPE is extremely rare in countries, such as the United States, where measles is no longer epidemic. However, in countries where measles is still endemic, it is still a relatively common occurrence.^{24,202,211,227,228,256}

Epidemiology

The estimated incidence of SSPE after wild-type measles virus infection in the prevaccine era was approximately one case per 100,000 population. The incidence of SSPE in the prevaccine era in some developing nations greatly exceeded that of developed nations. In southern India the incidence of SSPE was as high as 21 per 100,000 population,⁴²⁶ and in Pakistan the rate was estimated to be 100 per 100,000.²⁶⁶ A report from Papua New Guinea suggested a similarly high incidence of SSPE.²⁹⁶ Several characteristics of natural measles virus infection in developing countries in the prevaccine era were associated with the development of SSPE and included the high incidence of measles and the frequent occurrence of measles in children younger than 2 years. Both these risk factors for SSPE are modifiable, if not preventable, by vaccination.

The disease has been reported in all countries of the world, and although no outbreaks have been reported, clustering of cases prompted suggestions that environmental factors or unique strains of viruses may contribute to the development of SSPE after measles. The epidemiologic study of SSPE in the Netherlands described four cases of SSPE that occurred in 1 year in one city of 120,000 people, a number that calculated to four cases of SSPE per 6000 cases of measles, a rate 10-fold greater than that for the rest of the country.³³

The incidence of SSPE in the prevaccine era was approximately five times higher in the southeastern United States than that in other regions of the country,^{206,233,334} also suggesting the possibility of environmental cofactors. In addition, in the prevaccine era, a preponderance of cases of SSPE occurred in the United States, as well as in other developed and developing countries, in children from rural areas, independent of the incidence of measles in these areas.^{63,64,206,299,333} SSPE appears to have no racial predilection, although the largest number of cases occur in whites.^{231,334} The incidence of SSPE consistently is two to three times more common in male than in female patients.^{33,231} No relationship between any HLA genotype and the development of SSPE has been demonstrated, and cases of SSPE in only one member of identical twins have been reported.^{106,130,224} The usual age at presentation in the prevaccine era was between 6 and 10 years, with ranges of 2 to 35 years reported.^{33,164,165,206} The youngest case reported was in a 10-month-old child, and the oldest was in a 52-year-old man with depressed cellular immunity.^{39,459} In most cases, symptoms attributable to SSPE begin 4 to 8 years after measles virus infection; however, in some series, older patients (>10 years) appeared to have experienced a prolonged interval between measles virus infection and the development of SSPE.^{33,231,334}

Although several risk factors for the development of SSPE have been demonstrated repeatedly, the most consistent is the acquisition of measles before reaching the second birthday.^{33,129,206,334,426} An estimated minimum of 50% of those with SSPE have had early measles.²⁰⁶ In India, an estimated 60% of measles infections occurred before the patients reached 2 years of age, a factor possibly contributing to the high incidence of SSPE in the United States.⁴²⁶ Other risk factors have included exposure to animals.²⁰⁶

The decreased incidence of SSPE after institution of an effective measles vaccine program was demonstrated in several countries.^{33,51,89,91,326,375,486} The incidence of SSPE in the Netherlands decreased 10-fold after universal vaccination was initiated.³³ The incidence in Japan decreased at least 10-fold and possibly more.³⁷⁵ Development of SSPE after receipt of measles vaccination has been noted to occur. In a case-control study of patients with SSPE in the United States, 17 of 52 patients (32.7%) with SSPE had received measles vaccine before they developed disease.²⁰⁶ Similarly, SSPE occurring after measles

*References 7, 149, 153, 175, 195, 196, 241–243, 252, 316, 336, 350, 391, 397, 464.

immunization was noted in the Netherlands, but the incidence of vaccine-related SSPE was less than one case per 2.5 million immunizations.³³ In Japan, the estimated incidence of measles vaccine-related SSPE was 0.9 cases per million doses of vaccine.³⁷⁵ An inherent problem common to all of these studies was the inability to identify patients with subclinical, wild-type measles virus infection before they received vaccination. Subclinical measles virus infections are thought to be common in developing countries, as illustrated by studies from India that suggested that as many as 20% to 40% of patients with measles may have had a subclinical or unrecognized infection.⁴²⁶

In the United States, the success of measles immunization clearly resulted in a profound reduction in the incidence of SSPE.^{51,89,91,486} In the earlier years of the immunization program in the United States, rare cases of SSPE developed in vaccinees. Some of these children and perhaps all of them had unrecognized measles infection before they were vaccinated, and the SSPE was caused by the natural measles virus infection and not the vaccine virus.⁴⁸⁶ We are unaware of any cases of SSPE in the United States since the year 2000 that can be attributed to measles vaccine virus.

Bellini and associates³⁵ studied brain samples from 11 patients with SSPE during the period 1992 to 2003. Nine of the patients in this group had a history of measles immunization. Nonetheless, in all 11 cases, the measles virus genotype identified was that of wild measles and was not consistent with vaccine virus. These researchers attributed the measles infections to the epidemic that occurred in the United States from 1989 through 1991.

In the period 1989 through 1997, 55,622 measles cases were reported. From these data, a rate of 22 cases of SSPE per 100,000 reported cases of measles was calculated. This rate is approximately 10 times higher than previous estimates in the United States and similar to those noted in developing countries in the prevaccine era.^{266,296,426} In Germany, from 2003 to 2009, there were 39 SSPE cases. The rate of SSPE was calculated as one case per 1700 to 3300 measles cases in children less than 5 years of age.⁴³⁴

Pathogenesis and Pathology

Autopsy specimens from patients who died of SSPE reveal mild to striking changes in the gross appearance of the cerebral cortex, with ventriculomegaly in some cases. Histopathologic changes include minimal meningeal cellular infiltrate, with a perivascular accumulation of lymphocytes and plasma cells. Within involved areas of the brain, dense infiltrates of T lymphocytes and marked cellular expression of MHC class II antigens have been described.⁵⁶ A prominent microglial and astrocytic hyperplasia often is present. One of the characteristics of SSPE is the presence of intranuclear and cytoplasmic inclusion bodies.

The study of these structures by electron microscopy in 1965 led to the finding of paramyxovirus-like particles in autopsy material.^{54,463} Subsequently, Connolly and colleagues¹¹¹ described the presence of measles virus antibody in the CSF of patients with SSPE, as well as the presence of measles virus antigens in brain tissue from autopsy specimens of patients who had SSPE. Shortly thereafter, several laboratories reported the recovery of defective measles virus in specimens of brain from patients with SSPE.^{56,220,221} Virus was isolated only by cocultivation and not as cell-free material. Together, these findings suggested that SSPE was caused by a persistent infection of the brain by measles virus.

Several mechanisms, such as an abnormal host immune response to a common infection or a mutant virus, have elicited the most interest. Available data suggest that it may be a combination of these two possibilities. Several observations of the natural history of SSPE are consistent with an abnormal host immune response to a primary measles infection. They include the following: (1) the chronicity of measles virus infection in children with SSPE indicated a failure to eliminate the agent; (2) the importance of early acquisition of measles virus in the development of SSPE suggested that the immature immune system may predispose the host to a persistent infection; and (3) the onset of clinical disease long after a primary infection also suggested a failure of a previously protective immune response. Early on, the consensus was that patients with SSPE had subtle defects in cellular immune responses as measured by decreased cutaneous reactivity to common skin test antigens, decreased lymphocyte proliferative responses to mitogens and measles virus

antigens, and reduced production of cytokines. Subsequent studies failed to confirm these conclusions, and most investigators now suggest that patients with SSPE can generate vigorous cellular immune responses after exposure to mitogen and measles-specific antigens.⁵⁶ Studies demonstrated the presence of several cytokines, including IL-1b, IL-2, IL-6, TNF, heat-labile toxin, and IFN- γ , as well as other markers of immune activation, in brain lesions from patients with SSPE.⁵⁶ Still, some debate continues about the immunocompetence of patients with SSPE. Finally, measles virus is associated with chronic progressive encephalitis in immunocompromised patients (measles inclusion body encephalitis); however, the clinical course and histologic findings of this disease clearly are different from those of SSPE.

In contrast to the questions that surround the cellular response to measles virus in patients with SSPE, antibody responses to measles virus-encoded proteins are well preserved. Antibodies of all isotypes are produced peripherally and within the CNS. Antibodies against all the proteins encoded by measles, including the M (matrix) protein, have been detected in the sera from patients with SSPE.⁵⁶ The paradox of elevated levels of circulating antimeasles antibody as well as CSF antimeasles antibody in the presence of persistent infection suggested a possible immune-mediated origin of this disease. Evidence was presented that antimeasles antibody could interfere with spread of the virus and syncytial formation. Fujinami and Oldstone¹⁶⁴ demonstrated that antimeasles antibody reversibly could modulate the intracellular expression of measles virus-encoded proteins, thereby providing a mechanism by which antiviral antibody could convert an acute productive infection into a chronic persistent infection. This decrease in expression of measles antigen also could shelter virus-infected cells from immunologic recognition. This hypothesis also is supported by observations suggesting that early acquisition of measles predisposes the individual to the development of SSPE because the limited quantity of passively acquired maternal antimeasles antibody may be insufficient to prevent development of infection and dissemination of measles virus but adequate to modulate expression of measles virus. This series of events then would predispose the patient to the development of a chronic persistent infection. Animal models consistent with this disease mechanism have been described.⁵⁶

The second general mechanism for the development of SSPE is the generation of viral mutants during acute infection that then can establish a persistent infection. Persistence may result from antigenic variability or a viral mutation leading to decreased production of viral proteins below a level recognizable by the immune system or an extension of cell tropism. That measles viruses from the CNS of patients with SSPE are defective in replication is well documented. Analysis of these isolates does not define a virulence feature of SSPE strains but does suggest several mechanisms that could account for the generation of viral mutants. Much interest has been focused on the decreased expression of the M protein in explants of brain tissue from patients with SSPE.⁵⁶ This viral phenotype also was consistent with the decreased production of anti-M antibody in patients with SSPE, a finding suggesting the possibility of subthreshold production of antigen in these patients. Although the decreased expression of M protein was proposed originally as the mechanism for the persistence of mutant measles virus in patients with SSPE, subsequent studies showed that this is only one of many mutant phenotypes in strains of measles virus associated with SSPE.

Further studies of the replication of measles virus revealed several mechanisms that favor the production of mutant viruses. The RNA polymerase of measles viruses, like that of other RNA viruses, does not have proofreading functions and therefore frequently misincorporates nucleotides.⁶⁷ Thus mutant progeny virus arises regularly and can be selected either by host immune responses or because of its extended host-cell tropism. In addition to this general mechanism of genetic diversity in RNA viruses, measles virus also exhibits what has been described originally as biased hypermutation and more recently as A/I hypermutation.^{68,69} This mutational event results in clusters of U (uridine) to C (cytidine) or A (adenosine) to G (guanosine) transitions, possibly as the result of novel host-derived enzymatic activity referred to as *double-stranded RNA unwindase*.⁵⁶ This activity results in the replacement of A residues with inosines in duplex RNA molecules formed between genomic RNA and mRNA. Replication of the inosine-modified genomic

strand then results in the replacement of U by C. Evidence of this proposed mutational event has been found in the genomes of measles viruses from the brains of patients with SSPE, in which up to 132 of a possible 266 U residues in the M coding sequence were converted to C.⁶⁷

Studies clearly demonstrated that the M gene is the most heavily mutated of measles virus genes, often with early stop codons. Researchers stressed that this mechanism of genetic change is operative during lytic as well as persistent infection, and mutants that persist must do so as the result of growth advantage, such as evasion of the host immune response. The frequent mutations found in the M gene suggest that the measles virus can tolerate extensive genetic change in the M protein yet still replicate within cells of the CNS. The finding of clonal spread of a hypermutated measles virus genome within the brain of a patient with SSPE is consistent with this hypothesis.²⁸ Kweder and associates²⁸⁰ have noted that B3 genotype viral strains have not been associated with SSPE cases. These B3 strains do not have the PEA motif in their M protein. Other genes of the measles virus also exhibit mutations that alter function, including the gene encoding the hemagglutinin (H) protein. Mutations of this protein were shown to limit cell surface expression but not the function of hemagglutinin in the replicative cycle of measles virus.⁴¹ Cells infected with this phenotype likely are poorly recognized by the immune system because of the limited cell surface expression of the H protein, yet enough functional activity remains to allow spread of the mutant virus within the CNS by a mechanism of cell-to-cell fusion. Thus the generation of measles viruses that can induce disease and establish persistent infections results from viral strategies of genetic diversity coupled with selective pressure of the host immune response.

Clinical Manifestations

The initial stage of the disease can be described best as a period of progressive psychointellectual disturbances.^{202,413} These disturbances can include lability of mood, deterioration of school performance, hyperactivity or lethargy, depression, and occasionally altered states of consciousness. Although retrospective analysis often allows precise definition of the onset of SSPE to be established, many of these disturbances are so subtle that they escape parental or physician detection. Physical findings vary and often are nonspecific. A peculiar pigmented retinopathy has been observed in a small number of patients.⁶⁵ The duration in stage I varies, depending on the clinical staging system, but in larger series, this stage is relatively short, usually lasting fewer than 6 months.⁴¹³ The duration in stage I appeared to be prolonged in older patients compared with patients younger than 10 years in the series from the Netherlands.³³ Accelerated progression to stage II has been reported.⁴¹³

Stage II is characterized best by a variety of convulsive and motor disorders. The motor disorders are striking, ranging from akinetic drop attacks to violent myoclonic jerks. The motor disturbances have been described consistently as stereotypic and rhythmic. Rigidity or spasticity may be present in the later part of this stage.⁵⁶ Extrapyramidal findings, such as choreoathetotic and ballistic movements, as well as parkinsonism with abnormalities in the basal ganglia, have been reported. Intellectual functions continue to deteriorate, but patients may retain receptive function during this stage. In one series of patients, as many as 50% with stage II disease had abnormal retinal findings, including optic atrophy. The duration of this stage is quite protracted; as many as 50% of patients remain in this stage for longer than 6 months, and as many as 20% remain so for more than 1 year.

Progression to stage III is suggested by increased frequency of myoclonic jerks, development of spasticity or rigidity, and decerebrate and decorticate posturing. Hypothalamic dysfunction becomes prominent, with hyperpyrexia, diaphoresis, and periods of pallor and flushing. Cortical activity rapidly decreases, and patients usually become comatose in this preterminal stage of disease. Duration of this stage is relatively short, lasting fewer than 6 months in most cases. Death usually is associated with complications that accompany the vegetative state, although destruction of essential structures within the brainstem or hypothalamus may result in death.

The previous descriptions account for most patients with SSPE; however, a significant number may exhibit a less predictable course.

Some 5% to 10% of patients can be expected to have a prolonged survival measured in years. These patients may progress to stage II or III and then remain static without relapse, or they can experience a periodic and sometimes fatal relapse of disease. Conversely, some 10% of patients may have a fulminant, rapidly progressive course lasting less than 3 months.^{184,300,416}

Laboratory Findings

The definitive diagnosis of SSPE relies on a combination of laboratory findings and a compatible clinical course. Before the association between measles and SSPE was made, the electroencephalogram (EEG) was extremely helpful in establishing the diagnosis.^{160,161,306,413} The classic pattern of the EEG in SSPE is described as periodic, synchronous, bilateral discharges with a frequency of 3 to 20 seconds.¹⁰⁸ The discharge contains high-amplitude polyphasic slow-wave complexes, often consisting of two or more delta waves.³⁰⁶ Frequently, the background of the EEG is suppressed, thus creating the familiar burst suppression pattern. The EEG provides little help in predicting progression of SSPE. Also of note is that the absence of the classic findings, as well as other abnormalities on the EEG, has been reported in patients with SSPE.^{160,161,227,228,240} Alternatively, the finding of periodic generalized bursts of fast waves should prompt consideration of SSPE.³⁰⁹

More recent advances in imaging technology have aided greatly in the diagnosis of SSPE. Computed tomographic (CT) scans are abnormal in more than 50% of patients with SSPE, but the findings often are nonspecific.^{56,114,125,135,345} In the later stages of the disease, cortical atrophy often is a prominent finding on CT scan. Magnetic resonance imaging (MRI) of patients with SSPE has revealed the presence of focal lesions consistent with inflammation, often in the white matter, in multiple areas of the brain.¹²⁵ In some cases the location of abnormalities detected by MRI closely reflects the clinical symptoms of the patient, whereas in others the MRI findings do not correlate with clinical findings.⁴⁶² Finally, brain biopsy has been used as an important means of establishing the diagnosis in the past and still is of considerable value in atypical cases.

Perhaps the most useful laboratory examination of the patient with suspected SSPE is the examination of the CSF. Normal to slightly increased levels of protein with an absolute increase in the γ -globulin fraction are a consistent finding in patients with SSPE.²⁴⁰ Furthermore, the increase in the γ -globulin fraction is caused almost exclusively by elevation of immunoglobulin.^{443,480} Additional studies showed that 20% to 40% of the CSF IgG was oligoclonal and that the oligoclonal fraction contained antimeasles antibodies.^{474,475} This finding almost is pathognomonic for SSPE in patients with compatible clinical presentations. All isotypes of antibodies have been found in the CSF, although the finding of IgM antimeasles antibody remains controversial.^{56,141,222,482} Because the levels of antimeasles antibodies within the CSF are elevated, as well as oligoclonal, most investigators contend that these antibodies are produced locally within the CNS, apparently in response to ongoing measles virus replication. Other CSF findings include normal levels of glucose and slight pleocytosis consisting primarily of lymphocytes. Patients with SSPE have normal to elevated levels of circulating anti-measles antibody; in some cases, this antibody response also appears clonally restricted.⁵⁶

Treatment

In the past, 5-bromo-2-deoxyuridine, transfer factor, ribavirin, and amantadine proved to be of little value.⁵⁶ In the 1970s, the antiviral agent inosiplex was introduced and was thought to have antiviral activity *in vivo* and *in vitro*, although this claim remains controversial. Some studies suggested that treatment with inosiplex may result in stabilization, prolongation of survival, or actual clinical improvement in as many as 50% to 60% of patients. In a large study, 98 patients with SSPE were treated continuously, and their actuarial survival was compared with that of 500 historical controls.²⁴⁴ The results of this study showed that median survival for the treated patients was 3.2 years compared with 1.2 years for the historical controls. The use of historical controls, however, raised a number of questions about the validity of the results. The results of this trial also suggested a greater benefit of treatment with inosiplex in patients with more slowly progressive SSPE. Other studies

did not demonstrate any efficacy of inosiplex.⁵⁶ Inosiplex and intrathecal IFN- α seem to elicit transient improvement in some patients.^{136,137,279,301,332} IFN- β combined with inosiplex also may offer benefit in patients with SSPE.¹⁶ Other treatment approaches that may have shown some benefit in children include levetiracetam, ribavirin, amantadine, cimetidine, corticosteroids, plasmapheresis, and intravenous immunoglobulin.³¹

Measles in Developing Countries

Measles has been and continues to be a staggering problem in developing countries. The mortality rate in much of Africa was approximately 10%,³⁷² and a reasonable assumption is that the rates are similar in some regions of Asia.^{121,396,414,460} In developing countries, measles is a disease of young children. For example, in Kenya in the prevaccine era, 25% to 30% of children contracted measles before reaching their first birthday, and 55% to 60% did so before they were 2 years of age; virtually all children had measles by the time they were 4 years old.²¹² In Kenyan children, mortality peaked in the 17- to 20-month age group, and the median age for hospital admission was 14 months.

Although many factors, such as the age at infection, suboptimal medical facilities, and failure to seek medical care, contribute to the excessive morbidity and mortality in children of developing countries, the single overriding factor generally has been thought to be the nutritional status of the infected children.^{340-342,372} The data of O'Donovan³⁷² clearly indicate a direct relationship between malnutrition and hospital admissions for measles and deaths. Studies by Coovadia and colleagues¹¹³ and by Carney and associates⁶⁶ indicated both humoral and cell-mediated defects in protein-calorie malnutrition. The clinical picture of measles in children with malnutrition is frequently similar to that in patients with known defects in cell-mediated functions.

Low serum retinol concentrations nearly always are present in children with measles in developing countries.^{29,116,226,231,307,408,476} Low retinol levels correlate directly with measles mortality, and treatment with vitamin A reduces this mortality rate.^{29,226,307} Studies performed since the 1980s indicate that the intensive exposure that occurs in children in developing countries is a major factor in measles mortality.^{1,3,172}

Clinical Manifestations

Measles in children in developing countries is characterized by two different types of severe disease. One type of illness is a fulminant, toxic illness without apparent localizing complications. The other is a more prolonged illness with obvious complications; the complications may be caused by infection with secondary bacterial or other infectious agents, persistent measles virus infection, or a combination of both.

In a group of 507 hospitalized children, O'Donovan³⁷² noted that 301 had pneumonia, 96 had gastroenteritis, 36 had croup, 11 had convulsions, 67 had two or more complications, and 140 had nonlocalized systemic toxic effects. The measles rash in malnourished children tends to result in greater confluence and progresses to dark red and then violet.^{340,342} Desquamation is marked and occurs in large scales.⁴³⁰ After desquamation, patchy depigmentation lasts for some weeks. Other common problems are stomatitis and the resultant sore mouth, which leads to further loss of nutritional intake. Acute corneal ulceration, which occurs after measles in malnourished children, is a common cause of blindness.⁴²⁷ Multiple skin abscesses and noma (cancrum oris) are rare secondary infectious problems.²⁴⁷

Measles in Immunocompromised Hosts

Today, because of the extensive use of immunosuppressive therapeutic modalities and greater duration of survival in certain rapidly fatal diseases, a sizable population of children and adults is immunologically compromised. Measles virus infection in a patient with disease-induced or iatrogenically caused immune deficiency usually is severe and protracted and frequently is fatal.

The most common severe measles virus infection in an immunocompromised host is giant-cell pneumonia.^{141,264,320,329,330,406,442} The mode of manifestation of this illness varies. Some patients initially have severe but otherwise typical measles after a normal incubation period. Clinical findings at the time of the exanthem indicate pulmonary involvement and respiratory distress, and radiographic findings become rapidly worse over a period of about a week or less. Other patients initially have rather

vague illness, frequently without rash. In these cases, the pulmonary process may progress over the course of a month or longer. Siegel and associates⁴⁴² reported a child with leukemia who recovered from typical measles and then died the following year of diffuse interstitial pneumonia in which characteristic measles giant cells were seen.

A unique form of measles encephalitis also is manifested in immunosuppressed patients.^{8,160,161,208,321,345,348,403,469,497} Although the symptoms in different described cases varied, the illness appears to be intermediate between the acute encephalitis occurring in patients without known immune defects and the chronic picture of SSPE. The incubation period has varied between 5 weeks and 6 months.⁸ Convulsions frequently are the initial symptom, and they are a prominent aspect of the illness. The seizures have been focal, unilateral, or permanent localized twitching. Other findings include hemiplegia, stupor, coma, hypertonia, and slurred speech. Most cases have been fatal, and the duration of illness has been from 1 week to 2 months. It should be noted that successfully treated children with leukemia, solid tumors, and Hodgkin disease lose humoral immunity to measles and thus should all be revaccinated.⁵²

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of typical measles must include all illnesses in which an erythematous maculopapular rash occurs (see Chapter 58). The following are most important in establishing the diagnosis of measles: a consideration of possible exposure; the duration of the incubation period; the presence of Koplik spots; the presence of the typical febrile prodrome with cough, coryza, and conjunctivitis; and progression of the rash in a caudal direction. The brown discoloration and the intensity of the measles rash are such that the illness usually should not be confused with rubella, erythema infectiosum, roseola infantum, or enteroviral infection. Of greatest differential difficulty are the exanthems of infectious mononucleosis, *Mycoplasma pneumoniae* infection, and drug eruptions.

In the past, atypical measles was extremely difficult to diagnose. Today for children born in the United States, this disease will occur only in adults aged 50 years or older. The key to diagnosing this illness is careful elicitation of an accurate vaccination history. Even if it is not known whether the vaccination that the patient received as a child was live or killed vaccine, it usually can be determined by the number of doses given; if a child received more than one dose of vaccine in a short interval, killed vaccine almost certainly was administered. Differential considerations in atypical measles include Rocky Mountain spotted fever, anaphylactoid purpura, *M. pneumoniae* infection, and drug eruptions.

DIAGNOSIS

Measles virus infection can be diagnosed specifically by the following methods: isolation of virus in an appropriate tissue culture system; demonstration of measles antigen in exfoliated cells and tissues by FA techniques or polymerase chain reaction (PCR)³¹²; or the demonstration of a rise in HI, CF, ELISA, FA, or neutralizing antibody titer in two sequential serum samples or specific measles IgM antibody in a single serum sample (see Chapter 253).

In the recent past, measles was usually diagnosed by the demonstration of specific IgM antibody in an acute-phase serum specimen. False-positive IgM enzyme immunoassay results may occur.^{71,73,76,90,237,472} Perhaps more importantly, false-negative results may occur in secondary vaccine failure cases. These patients may have vigorous IgG measles antibody response but no IgM response. Therefore, today, the preferred diagnostic method is the detection of measles RNA by reverse transcriptase PCR or by culture.^{72,74} Virus can be detected in samples from the throat, nasopharynx, and urine.

TREATMENT

Uncomplicated Measles

No specific therapy for uncomplicated measles exists. During the febrile period of illness, activity should be discouraged, and fluid status should be maintained by the liberal provision of soft drinks and ice. Fever may

be controlled with acetaminophen. Coughing frequently is distressing and can be managed by the judicious use of common antitussive agents. Room humidification also is useful in controlling the cough and generally can be expected to make the patient more comfortable. As the fever disappears, a gradual return to normal activity is indicated. However, measles virus infection is associated with considerable damage to the ciliated epithelium of the respiratory tract; therefore, resumption of normal activities too soon and exposure to other children and their bacterial pathogens can be associated with severe secondary infection.

Children in developing countries frequently have vitamin A deficiency. Measles morbidity correlates with this deficiency, and treatment with vitamin A is beneficial.^{29,116,226,231,307,408,476} Studies in the United States indicate that vitamin A levels are low in a substantial number of measles cases and that morbidity is increased in these deficient children.^{12,19,62,162} Vitamin A supplementation also has been shown to enhance IgG antibody levels and total lymphocyte numbers.¹¹⁷ In 1993, the Committee on Infectious Diseases of the American Academy of Pediatrics recommended providing vitamin A supplementation for children with measles in selected circumstances.^{12,14} Vitamin A was recommended for children aged 6 months to 2 years who require hospitalization and all patients 6 months or older with immune deficiencies or possible vitamin A deficiency. The World Health Organization now recommends vitamin A for all children with measles in all countries.^{12,13} The doses are: 200,000 IU for children 12 months or older; 100,000 IU for infants 6 through 11 months of age; and 50,000 IU for infants younger than 6 months of age. Following this, an additional age-specific dose should be given 2 through 4 weeks later in children with clinical signs and symptoms of vitamin A deficiency.

Atypical Measles

The most important aspect of therapy for atypical measles is proper diagnosis. In patients with atypical measles, Rocky Mountain spotted fever, other septic conditions, lymphoma, or collagen vascular disease frequently is diagnosed erroneously, and their workup is associated with extensive blood cultures, other diagnostic procedures, and vigorous antibiotic therapy. Careful attention given to a history of previous administration of killed measles vaccine should clarify the diagnosis and preclude the unnecessary trauma associated with extensive diagnostic and therapeutic procedures.

In atypical measles, chest radiographs always should be obtained because the pneumonia that usually develops in these patients frequently is much more extensive than the clinical findings would indicate. Activity should be discouraged in acutely ill patients, and follow-up chest radiographs should be used as a guide to resumption of normal activity. In some patients, pulmonary abnormalities have persisted for a considerable period.

Complications of Measles

Otitis Media

Otitis media is the most frequent complication of measles. The infectious agent of otitis media in measles is no different from that in other children without measles of comparable age, so conventional antibiotic therapy is all that is necessary (see Chapter 16).

Laryngotracheitis

Management of the laryngotracheitis caused by measles virus infection is similar to that in other patients with croup caused by other viral etiologic agents. Administration of corticosteroids is contraindicated in measles, and antibiotics are indicated only in patients with laboratory or clinical evidence of secondary bacterial infection (see Chapter 18).

Pneumonia

Pneumonia is a common complication of measles, and it is the leading cause of death. Pneumonia may be a manifestation of primary viral infection, or it may result from a superimposed bacterial infection. The differential diagnosis between primary viral and superimposed bacterial disease cannot be made with certainty. Because the diagnosis of viral pneumonia often is uncertain, most patients should be treated with antibiotics. In primary measles pneumonia, treatment with aerosolized ribavirin should be considered.

In one uncontrolled study in adult patients, intravenous ribavirin was found to be well tolerated, and its use was associated with clinical improvement.¹⁵⁵ In a study in pregnant women, Atmar and associates²³ were unable to demonstrate clear clinical benefit with the administration of aerosolized ribavirin.

Encephalitis

The course of measles encephalitis is unpredictable, and treatment is symptomatic and supportive. Trained nursing care is essential. Careful attention given to fluid and electrolyte balance is necessary. In prolonged states of coma, parenteral hyperalimentation is indicated. Status epilepticus should be treated vigorously with the use of a structured protocol for ensuring optimal control (see Chapter 36).

Numerous review articles indicate that measles encephalitis is a postinfectious encephalitis and is predominantly a disease of white matter (ADEM).^{192,241,242} This concept resulted from a study of 19 patients with measles encephalitis that was published in 1984 by Johnson and associates.²⁴³ I am aware of only two patients subsequent to this article who had ADEM associated with measles virus infection. Clinical evidence supports the finding that ADEM not related to measles virus infection is responsive to corticosteroid therapy.^{152,315}

Considerable evidence indicates that measles encephalitis usually is not ADEM and that active direct CNS infection is involved in the process.^{143,153,316,392,464} A controlled trial of 32 children with measles encephalitis failed to find benefit in the corticosteroid-treated group.⁵¹⁰ These data suggest to us that corticosteroids should not be used to treat measles encephalitis unless evidence of ADEM is clear and active measles virus infection has subsided. In patients with severe intractable seizures or other evidence of cerebral edema, the use of intravenous mannitol therapy (0.25–1 g/kg of a 20% solution administered over the course of a 30- to 60-minute period) is indicated. In occasional circumstances, respiratory arrest is a problem, and artificial ventilators should be used to tide patients over until respiration becomes normal. Mustafa and coworkers³⁴⁸ noted improvement in an immunocompromised child with subacute measles encephalitis who was treated with intravenously administered ribavirin.

Appendicitis

Acute abdominal pain occurs occasionally in primary measles, and it can be caused by generalized mesenteric adenitis secondary to measles virus appendicitis. In appendicitis, evidence of measles virus involvement of the appendix is present. However, therapy should be similar to that in other cases of appendicitis; removal of the appendix is indicated because measles appendicitis perforates with a frequency equal to that in non-measles virus infection.

Prophylactic Antibiotics

In the developing world, secondary bacterial infections in measles are a major cause of mortality. Accordingly, interest has arisen in the use of antibiotics prophylactically.^{93,437} A meta-analysis in 1997 of studies involving the use of prophylactic antibiotics noted that the available data were poor and provided only weak evidence for giving antibiotics to all children with measles.⁴³⁷ The recommendation from this study was that antibiotics should be given only if a child has clinical signs of pneumonia or other evidence of sepsis. Chalmers⁹³ pointed out the necessity and urgency for performing controlled prophylactic trials.

PREVENTION

Active Immunization: Live, Attenuated Measles Virus Vaccine

The original attenuated measles vaccine was developed from the Edmonston strain of measles virus by passage in human kidney and human amnion tissue cultures, then in chicken embryos, and finally in chicken embryo fibroblast tissue culture.⁴⁵⁵ Today in the United States, measles vaccines are prepared in chicken embryo fibroblast tissue culture. Vaccines available in other countries are prepared in chicken embryo fibroblast tissue culture, Japanese quail tissue culture, chicken embryo, and WI-38 tissue culture. Vaccination produces a mild or inapparent noncommunicable infection that induces active immunity in more than 95% of recipients. Following two doses of a measles-containing vaccine,

99% of vaccinees will be immune, and this immunity is long-lasting.^{273,277,278} However, the decay in antibody values over time with the present measles vaccine used in the United States is greater than that following natural infection. It was noted by Chen and associates^{96,308} that low levels of measles antibody (values <120 IU) were not protective against infection and illness. Today, there is a large population of previous two-dose vaccine recipients who have not had natural antibody boosts from wild virus exposure. Many of these people will get measles when exposed. One of us (J.D.C.) with colleagues at the California Department of Public Health has analyzed measles cases between 2000 and 2015 in California (J.D. Cherry and J Zipprich, unpublished data). In this study, 29 instances of secondary vaccine failure were noted. Illness in these patients was less severe than primary infections, and the patients were less contagious. Similar findings were noted in Canada in an epidemic in 2011.¹²²

Symptoms associated with measles immunization are minimal and are limited to fever, mild malaise, and occasionally a faint rash occurring approximately 1 week after immunization. For complete information and recommendations related to measles immunization, refer to Chapter 245 and the most recent recommendations of the Advisory Committee on Immunization Practices,²² the CDC "Pink Book,"^{78,92} the Committee on Infectious Diseases of the American Academy of Pediatrics,^{12,13} and the manufacturer's package insert. The vaccines in routine use in the United States today are measles-mumps-rubella (MMR) or measles-mumps-rubella-varicella (MMRV). Only a summary of recommendations is presented here.

Recommendations for Use

The widespread epidemics of measles in the United States in 1989 to 1991 were the result of a failure to immunize children at the appropriate age and the increased number of susceptible older children and adults because of vaccine failure.^{21,82,83,90,287,308} Therefore continued eradication of measles in the United States depends on ongoing programs that (1) enroll all children of initial vaccination age and (2) allow revaccination of all persons whose primary vaccine failed. Because routine immunity testing is not a viable public health option, revaccination of primary vaccine failures can be accomplished only by universal reimmunization.

Currently, live measles vaccine is recommended in a two-dose schedule.^{12,13,82,486} In general, live measles vaccine is recommended to be administered at 12 to 15 months of age and the second dose at entry into school.^{9,12,13,22,79,84,273,277,438,486,493,505} However, the second dose can be given after any interval longer than 1 month after administration of the first dose.^{29,78,92} Because of numerous importation cases in the United States in recent years, it is our opinion that the second dose of measles-containing vaccine should be given in the second year of life. The rationale for this suggestion is based on the fact that the one dose vaccine failure rate is 5%. Therefore, in the age group of 1 to 4 years, there are presently about 800,000 young children in the United States who are susceptible. Children who have not received vaccine during infancy may be immunized at any age, and adults who have not had natural measles also should be immunized. When measles is endemic or epidemic in a community, all children aged 6 months or older should be immunized. In children who initially were vaccinated before they were 12 months of age, a second vaccination should be administered at 12 to 15 months of age, and a third dose at entry into school is necessary to complete the schedule.

It should also be noted that persons born between 1962 and 1981 usually had received just one dose of vaccine. Many of the vaccine failures in this group will have been protected by herd immunity. In our opinion, persons in this group should be offered a second dose of a measles-containing vaccine or have their serum tested for measles IgG antibody.

Precautions

Measles vaccination should be deferred at times of febrile illness or when interference from another viral infection could cause failure of measles vaccine. Measles immunization also should be postponed for 3 to 11 months in persons who have received whole blood, blood plasma, or immunoglobulin because these products may contain sufficient measles antibody to neutralize the vaccine virus. The duration of

postponement depends on the product administered and the dose.^{12,13,22} Children treated with intravenous immunoglobulin for Kawasaki disease should not receive measles vaccine until 11 months after receiving the immunoglobulin, whereas 3 months' time is adequate for children given immunoglobulin for hepatitis A prophylaxis.

Contraindications

Live measles vaccine should not be administered to pregnant women or to some persons with diseases or therapeutic programs associated with impaired cell-mediated immunity. These conditions in general include the following: leukemia, lymphoma, or other generalized malignant diseases; primary and secondary immunologic disorders; and therapy with corticosteroids, radiation, antimetabolites, or alkylating agents. Measles immunization is recommended for children and adults with asymptomatic human immunodeficiency infection and for symptomatic patients who are not severely immunocompromised.¹²⁻¹⁴

Complications

Serious complications associated with administration of measles vaccine are exceedingly rare. Serious neurologic disease (encephalitis, Reye syndrome, cranial nerve palsy, cerebellar ataxia, and Guillain-Barré syndrome) within 30 days of immunization occurs at a rate of approximately one case per million doses of vaccine administered.^{76,83,284} This rate is lower than the rate of occurrence of encephalitis of unknown cause in children for any 30-day period. However, the clustering of cases on days 8 and 9 after immunization noted from claims submitted to the National Vaccine Injury Compensation Program suggests that a causal relationship between measles vaccine and encephalopathy may be a rare complication of immunization.⁴⁸⁷ In addition, recovery of measles virus from the CSF of a vaccinated child with encephalitis also suggests that rare vaccine-induced neurologic disease may occur.¹⁵³ In a large population-based study in Denmark between 1991 and 1998 it was found that MMR immunization was associated with a transient increased rate of febrile seizures.⁴⁷⁷ However, the long-term rate of epilepsy was not increased in children who had febrile seizures after receiving vaccination compared with children who had febrile seizures related to other causative events. Studies in the United States and Canada also noted an increased risk for febrile seizures during the first 2 weeks after the first dose of MMR.^{88,92} Further study noted that the risk for febrile seizures was significantly greater after MMRV than after MMR.^{260,280,298} In a recent study, Klein and associates²⁶⁰ found no increased risk for febrile seizures after the second dose of measles-containing vaccines in children 4 to 6 years of age. Thrombocytopenic purpura, anaphylaxis, hearing loss, and toxic epidermal necrolysis also have been associated with measles immunization.^{11,27,32,236,428,439,454,492}

In developing countries, high-titer measles vaccines were used to induce seroconversion at a young age.⁴⁹⁸ However, follow-up studies in some countries noted that the mortality rate was increased in female recipients of these high-titer vaccines over the course of a 3-year period compared with children who received conventional doses of vaccine.^{218,261} Nonetheless, follow-up studies in other countries showed no increased mortality rates in recipients of high-titer measles vaccine.^{3,288}

Global Progress Toward Measles Eradication

Measles has been a major cause of death in the developing world, with 750,000 deaths in 2000.⁸⁷ A World Health Organization (WHO) global immunization vision meeting in 2005 established a commitment to achieve a 90% reduction in measles mortality by 2010 compared with 2000.⁴⁹⁹ This commitment focused on 47 priority countries in the developing world. The components of the strategy included achieving and maintaining high coverage (>90%) with routinely scheduled first dose of measles-containing vaccine among children aged 1 year and ensuring that all children receive a second opportunity for measles immunization. In 2007, 82% of the target population was vaccinated, but the coverage varied substantially by geographic region. During the period 2000 through 2007, the global measles mortality rate was reduced by 74% (from 750,000 deaths in 2000 to 197,000 deaths in 2007).

Endemic measles has been eliminated in North America, Sweden, Finland, and selected other countries in the world. In the WHO

European Region (EUR), substantial progress was made between 2003 and 2009 in eliminating measles.^{77,89} However, since late 2009, measles outbreaks have become widespread. In 2010, 30,639 measles cases were reported in the EUR, and up to October 26, 2011, an additional 26,074 cases were reported. Most of the cases occurred in the western European subregion.

In 2011 in the EUR, 49.4% of the cases occurred in persons 15 years or older, 25% occurred in children younger than 5 years, and 24.7% occurred in children 5 to 14 years of age.^{77,89} Of the reported cases in 2011, 54% occurred in France and 11% in Spain. Nine deaths occurred (six in France), and seven of these occurred in persons older than 10 years. In 2011, 90% of the cases occurred in unvaccinated persons or in persons with an unknown vaccination status.

In the EUR, the overall coverage with at least one dose of a measles-containing vaccine is below the target of 95%.^{77,89} This is a particular problem in the western European subregion.

There are multiple reasons for the underuse of vaccines in the EUR.^{77,89,346} In contrast to North America, compulsory school immunization laws do not exist in Western Europe. Some degree of herd immunity has allowed unvaccinated children to become susceptible adolescents and adults. Important and serious barriers to increasing population immunity in the EUR and, in particular, the western European subregion, are religious or philosophical objections to vaccination.³⁴⁶

Perry and associates³⁹⁶ reviewed the progress toward regional measles elimination worldwide from 2000 to 2014. During the observation period, there was an increase in worldwide coverage with both first dose and second dose of measles-containing vaccines. There was a 73% decrease in reported measles incidence and a 79% reduction in estimated measles mortality. However, it was also noted that the 2015 goals of the WHO global vaccine action plan for 2011 to 2020 will not be met.^{499,500}

Quarantine and Disease Containment

Before the use of measles vaccines became widespread, quarantine measures were practiced widely but were largely ineffective in preventing the spread of measles. However, containment of disease is practical today because the widespread use of measles vaccine has reduced the general number of susceptible young children and thus has decreased the rapidity of epidemic development. Epidemic measles now generally involves a greater age range of the population (cases in adolescents and young adults occur frequently), and progression of disease from one age group to another is slower than in epidemics that involve one uniform, largely susceptible population.

Containment is a vital part of the measles prevention policy in the United States. Measles is a reportable disease throughout the United States, and compliance is the obligation of all physicians. After receiving early reports of sporadic measles, health department workers can organize local immunization clinics so that the disease often can be contained in a small geographic area rather than developing into a widespread epidemic.

Passive Immunization: Immunoglobulin

In the present vaccine era, there should be little need for passive immunization. However, as seen in California in 2014 and 2015, there were a significant number of exposed personal-belief, nonvaccinated children and also exposed infants too young to have been vaccinated. Passive immunization is highly effective when given 7 days of exposure.^{507,508} When a known susceptible child has had definite exposure to measles, immunoglobulin should be administered in a dose of 0.25 mg/kg (maximal dose, 15 mL). If this treatment is administered within 5 days of exposure, prevention of infection and disease can be expected. Administration of immunoglobulin later in the incubation period may modify the illness but does not prevent it. The use of immunoglobulin is particularly important in children who have not been immunized because of the contraindications to vaccination mentioned previously. In these children, immunoglobulin (0.5 mL/kg; maximal dose, 15 mL) should be administered when measles is epidemic in the community in which they reside. The dosage should be repeated every 4 weeks until the epidemic subsides. Intravenous immunoglobulin in a dose of 400 mg/kg may be used (also see Chapter 246).

Mumps (epidemic parotitis) is an acute communicable disease caused by the mumps virus, a member of the genus *Rubulavirus*. As a result of universal immunization, mumps was an uncommon disease in children in the United States at the end of the 20th century; however, a 2006 epidemic and subsequent outbreaks indicate the need for renewed study of mumps. In addition, mumps continues to be an epidemic problem worldwide.

HISTORY

In the fifth century BCE, Hippocrates described an outbreak on the island of Thasos.^{115,227} He noted that most patients had bilateral swelling near the ears and that the others had unilateral swelling. He also noted that some patients had bilateral or unilateral pain and swelling of the testes.

The origin of the name mumps is not known. It may be from the English noun *mump*, which means “a lump,” or the English verb *mump*, one of whose definitions is “mumble.” This latter possible origin is based on the mumbling speech that patients with significant parotitis may have.

In 1790, Robert Hamilton^{85,86} presented an extensive study of mumps in which he noted orchitis, associated the illness with neurologic involvement, and described the neuropathology of a fatal case. In 1886, Hirsch⁹⁷ noted that mumps occurred throughout the world and that it was a major cause of morbidity in Confederate troops during the American Civil War. In the first half of the 20th century, investigators recognized that mumps virus infection involved multiple organs, and the causative agent was shown by Johnson and Goodpasture in 1934^{59,108} to be a filterable virus.

The growth of mumps virus in embryonated eggs was reported in 1945, and 10 years later its propagation in tissue culture was noted.^{83,90} This latter development led to the development and licensure in the United States of a live attenuated mumps vaccine in 1967.

CLASSIFICATION

Mumps virus is a member of the genus *Rubulavirus*, subfamily Paramyxovirinae, and family Paramyxoviridae.¹³³ It contains a single-stranded, nonsegmented, negative-sense RNA genome that is surrounded by a helical nucleocapsid and a surface envelope.

PROPERTIES

Physical Properties

The virus generally is spherical, but marked pleomorphism occurs.^{117,132,183} Its size varies from 100 to 600 nm. The mumps viral genome is 15,384 nucleotides in length and encodes for 9 known viral proteins: a nucleocapsid-associated protein (NP), a phosphoprotein (P), a membrane or matrix protein (M), a fusion protein (F), a hydrophobic membrane-associated protein (SH), a hemagglutinin-neuraminidase (HN), a polymerase protein (L), and nonstructural proteins within the P protein (I and V, which counteracts the interferon [IFN]–induced host antiviral response).²²⁸ The genes for these proteins have been sequenced, and the gene order is 3-NP-P-M-F-SH-HN-L-5. The viral envelope is studded with 12- to 15-nm projections that contain either of the two structural glycoproteins (HN or F).

The P structural protein is associated with the nucleocapsid, and an RNA-dependent RNA polymerase is located within the nucleocapsid structure. The envelope has a high lipid content, and it contains the M protein.

The SH protein gene is the most variable region of the genome and therefore can be used to differentiate viral strains.^{5,122,163,202} Analysis of the variations in SH gene nucleotide sequences has been used to study outbreaks, identify vaccine viruses, study vaccine adverse events, and identify new viral strains. Antigenic differences among vaccine strains result in variable cross-neutralization of unknown significance.¹⁵¹

Mumps virus infectivity is destroyed by heat (56°C for 20 minutes), and its infectivity is reduced by ultraviolet light, Tween 80, ether, and formalin. The virus is stable at 4°C for several days; and when placed in a buffered salt solution (e.g., Hanks) with 1% to 2% inactivated fetal calf serum, the virus can be stored indefinitely at –70°C.

Antigenic Composition

The three major antigenic components of mumps virus are the two glycoproteins (HN or V antigen and F protein) and the nucleocapsid protein (NP or S antigen).¹¹⁷ The glycoproteins that project from the viral surface are the antigenic target for specific antibodies. Host antibodies to HN and F proteins confer protective immunity against the virus. Mumps viral particles agglutinate erythrocytes of several mammalian and avian species (human, avian, rodent, and simian); at 37°C, the virus causes partial hemolysis of susceptible erythrocytes when it is attached to cellular surface receptors. Specific antibody blocks hemagglutination, hemadsorption, and hemolysis.

Mumps virus is considered to have a single immunotype. However, polyclonal antibodies to parainfluenza and Newcastle disease viral antigens cross react with antibodies to mumps virus in complement-fixation and hemagglutination-inhibition assays. With monoclonal antibodies, an antigenic relationship between the NH and NP proteins of Sendai virus (a murine parainfluenza type 1 virus) and mumps virus has been demonstrated.¹⁶⁴

Although mumps is a monotypic virus, genetic variation among strains exists. A standardized nomenclature and an analysis protocol have been proposed for the genetic characterization of mumps strains to facilitate the expansion of molecular epidemiologic studies.^{106,107} This nomenclature includes 12 genotypes assigned letters from A to N (excluding E and M) based on the nucleotide sequence of the hydrophobic (SH) gene. The 2004 to 2005 UK outbreak and the 2006 US outbreak were of serotype G,^{37,178} whereas the F serotype is most prevalent in recent Chinese outbreaks.¹³⁹ Historically, C, D, G, and H predominate in the Western Hemisphere, and B, E, and I occur in Asia.¹⁰² The Western Hemisphere tends to use vaccines to the A serotype.²²⁸

Tissue Culture Growth and Animal Susceptibility

Mumps virus can be propagated in many different primary and cell-line tissue cultures.^{117,136} To isolate the virus, primary monkey kidney cells generally are used. Its cytopathic effect is similar to that of other paramyxoviruses. When the virus is stained, multinucleated giant cells and cytoplasmic eosinophilic inclusions may be observed. In culture, the addition of erythrocytes results in hemadsorption to surface virus.

Mumps virus infects monkeys, rabbits, dogs, cats, and rodents. The virus is isolated readily after inoculation of the amniotic sac of 7- to 8-day-old chicken embryos.

EPIDEMIOLOGY

Incidence

In the United States, mumps was a reportable disease from 1922 to 1950 and has been again since 1967. Between 1950 and 1967, incidence data were gathered from voluntary reporting by cooperating states. Incidence data from 1922 to 1982 are presented in Fig. 181.1, and

FIG. 181.1 Incidence of reported mumps in the United States from 1922 to 1982 and the number of reported cases from 1968 to 1982. (From Centers for Disease Control and Prevention. Mumps—United States, 1983–1984. *MMWR Morb Mortal Wkly Rep.* 1984;33:533–5.)

vaccine-era data are presented in Fig. 181.2.^{30,41} In the prevaccine era, mumps was a yearly disease, with epidemic peaks occurring approximately every 4 years. The peak epidemic year was 1944, when the rate was 250 per 100,000 population.

In the prevaccine era, mumps was a disease predominantly of young children.³⁰ However, outbreaks of mumps were a significant problem in young adults in the military.^{77,147} The age distribution of mumps in the United States during selected years is presented in Table 181.1. After the mumps vaccine was licensed in 1967, mumps remained a disease of predominantly young children from 1967 to 1971. However, by 1981, most reported patients were 10 years old or older. In 1987, 76% of the cases occurred in persons 10 years old or older (see Table 181.1). In 1994, 1537 cases were reported, and of those with age noted, 21.8% were in patients 20 years old or older. The increase in reported cases that occurred in 1987 (see Fig. 181.2 and Table 181.1) was the result of a marked increase in cases in nonimmunized persons 10 to 19 years of age. This group had been protected for a time by herd immunity because of the rapidly declining incidence of mumps as a result of routine vaccine use beginning in 1977.⁴⁷ In 1998, only 666 cases of mumps were reported in the United States.³⁴ Nineteen percent of the patients were younger than 5 years old, and 36% were 15 years old or older. In 2010, 54.6% of the reported cases were in persons 15 years of age or older (see Table 181.1).

In the prevaccine era, the peak incidence of mumps occurred in the winter and spring months, and this peak continued well into the vaccine era.^{29,77,120} After licensure of the mumps vaccine, reported cases in the United States dropped from 152,209 cases (87.9 cases per 100,000 persons) in 1968 to less than 300 cases (<0.1 case per 100,000 persons) from 2001 through 2005.^{36,28} However, a 2006 outbreak in primarily Midwestern college student populations revealed a dramatic resurgence of disease.^{36,38,39} By March 28, 2006, a total of 219 mumps cases were reported in Iowa alone; this was a 44-fold increase in cases from the preceding decade. Of the 219 cases, the median patient age was 21 years (range, 3 to 85 years), with 48% of the patients 17 to 25 years old; 30% of the patients

were known to be college students. This outbreak in Iowa in December 2005 was found to involve 10 additional states by May 2, 2006.³⁸ A total of 6584 cases were reported nationwide.^{35,56} There were 85 hospitalizations, 85% of patients lived in eight contiguous Midwestern states, and 83% were college students. Sixty-three percent of the case patients with known vaccination status had received two doses of either mumps or mumps-measles-rubella (MMR) vaccine, and affected colleges reported 84% two-dose MMR vaccine coverage. The year 2006 represented a historical national two-dose coverage peak of 87% among adolescents.^{16,51,56,144}

In 2004 to 2005, a mumps epidemic occurred in the United Kingdom.³⁷ There were 56,390 reported cases. In 2004, 79.1% of the confirmed cases were in persons 15 to 24 years of age, and two-thirds of all cases occurred in persons who had not been vaccinated. In many respects, this epidemic is similar to the one in the United States in 1987; herd immunity had protected this adolescent and young adult cohort for a number of years.*

A 2009 to 2012 mumps outbreak in the New York–New Jersey area had 3502 cases.¹⁷ The index case in this outbreak was a twice-vaccinated 11-year-old boy who returned to the United States from the United Kingdom on June 17, 2009. At the time of this boy's visit to the United Kingdom, there was a continuing large outbreak of mumps in the region. After returning home, this boy attended a camp in Sullivan County, New York. At the camp, he developed mumps. At the camp, there were 400 Orthodox Jewish boys. Of this group, 22 campers developed mumps, as well as three adults. The 25 camp cases were the index cases for 1813 cases in New York City, 449 cases in Rockland County, 425 cases in Ocean County, NJ, and 790 cases in Orange County, NY.

Of the 3405 cases in the outbreak, 97% occurred among Orthodox Jewish persons. Seventy-one percent of the cases occurred among male patients. Twenty-seven percent of the cases occurred in adolescents 13

^BIncludes all reported cases in patients age ≥15 years. Data from references 30, 41, and 214.

to 17 years of age. Of the 2317 patients (68%) in whom vaccinated status was verified, 10% were unvaccinated, 14% had received one dose of MMR, and 70% had received two doses of MMR vaccine.

A small outbreak of 29 cases on a university campus occurred in California in 2011. The presumed source patient was an unvaccinated student with a history of recent travel to Western Europe.⁴⁰

Worldwide recent outbreaks have occurred in the United Kingdom (2013),² France (2013),⁷⁵ Belgium (2012–13),²² the Czech republic (2011–12),¹³⁷ Bosnia and Herzegovina (2010–11¹⁰¹ and 2010–12¹⁰⁰), Germany (2010–11),²⁰⁶ Guam (2009–10),¹⁴¹ the Netherlands (2007–09²²⁶ and 2009–12^{64,80,131,186,225}), Canada (2007–09²²⁶ and 2009–10²¹⁷), Spain (2007–08),⁷⁶ Poland (2009),¹⁶⁷ Israel (2009–10),^{152,199} Scotland (2010–11),²¹⁶ Moldova (2007–08),¹⁸⁸ Macedonia (2008–09),¹²⁹ Australia (2007–08),¹⁴ the United Kingdom (2003–06),¹⁰⁵ Luxembourg (2008),¹⁵⁰ Palestinian refugee camps of the West Bank (2003–05),⁹⁶ Serbia (2012),¹⁵⁴ Portugal (2012–13),⁵⁰ and Denmark (2013).²⁰⁰

Morbidity and Mortality

The most common clinical manifestations of mumps virus infection are fever and parotitis. However, approximately 30% of infected persons do not have parotitis and therefore are not recognized.¹¹⁹ Epididymo-orchitis occurs in 20% to 30% of clinical cases in postpubertal male patients. Approximately 60% of clinical mumps cases involve cerebrospinal fluid (CSF) pleocytosis, but only one-sixth of these patients have

meningeal symptoms.¹³ In 1966, 628 cases of encephalitis (0.5% of total reported cases) were reported, and of these, 10 (1.6%) had a fatal outcome.³¹ Encephalitis occurs more frequently in male patients (61%) than in female patients (39%), and the rate of occurrence is greatest in adults. Deafness after a case of mumps has been estimated to occur in 0.5 to 5.0 per 100,000 cases.^{63,215}

From 1966 to 1975, 200 mumps-associated deaths were reported in the United States.³¹ Of these, 44 (22%) were in patients with encephalitis; in the others, the causes of death were not identified. Forty-one percent of the deaths occurred in adults 40 years old or older. During the 10-year period from 1988 through 1997, only eight deaths caused by mumps were reported.³⁴

In the 2006 mumps outbreak in the United States there were 85 hospitalizations (2%), but no deaths were reported. Parotitis or other salivary gland inflammation was reported in 99%, nonspecific symptoms (headache, myalgia, or fatigue) in 57%, and fever in 29%. Overall complications were 5%, with orchitis most prevalent. Encephalitis and meningitis occurred in less than 1%.⁵⁶

Spread of Infection

Mumps virus is contagious for nonimmune persons. It is spread from an infected person to a new host by the respiratory route. The virus can be isolated from the saliva of infected patients from 7 days before the onset of parotitis to 9 days after onset.¹¹⁷ Transmission is greatest

during a 7-day period beginning 2 days before the onset of parotitis. Asymptotically infected persons also can transmit the virus. The finding that outbreaks of mumps occurred in young adult populations in the prevaccine era suggests that mumps virus is less contagious than is measles; a significant number of persons passed through childhood without being infected with mumps virus. In 2011, the Centers for Disease Control and Prevention (CDC) discontinued conducting airline flight-related mumps contact investigations after prior investigations failed to reveal any secondary cases among passenger contacts.¹⁵⁶ A serologic study reported by Black²⁰ in 1964 noted that 24% of US Army recruits lacked hemagglutination-inhibition antibody to mumps, whereas only 1% lacked measles antibody. The incubation period usually is 16 to 18 days, although it can vary from 12 to 25 days.¹¹⁷

PATHOGENESIS

After respiratory or perhaps oral acquisition of the virus, primary viral replication occurs in the upper respiratory mucosal epithelium.^{65,117,227} Virus multiplies and is spread by drainage to local lymph nodes.⁶⁵ Subsequently, viremia develops.^{112,166,211} As a result of viremia, infection occurs in multiple secondary infection sites. Mumps virus prevents macrophage chemotaxis through a soluble factor released from infected cells.²³ Most prominent is infection of the salivary glands, which results in inflammation and swelling. This infection causes virus shedding for 1 to 2 weeks. Other secondary sites of infection include the inner ear (cochlea), pancreas, heart, nervous system (meninges and brain), joints, kidneys, liver, gonads, and thyroid.

PATHOLOGY

In the salivary glands, virus infects the ductal epithelium and causes periductal interstitial edema and a local inflammatory reaction involving lymphocytes and macrophages.^{180,224,227} Tissue damage ensues, and the involved cells desquamate. Virus enters the central nervous system (CNS) by the choroid plexus through infected mononuclear cells. Virus multiplies in choroid and ependymal cells on the ventricular surfaces, and these cells desquamate into the CSF and result in meningitis. In encephalitis, perivascular infiltration with mononuclear cells, scattered foci of neuronophagia, and microglial rod-cell proliferation occur.²⁵ Periventricular demyelination also takes place. In the male gonad, the primary site of viral replication is the seminiferous tubules, where infection results in lymphocytic infiltration and edema of interstitial tissue.

Immunologic Events

Infection gives rise to serum antibodies to the HN glycoprotein (V antigen), the F antigen, and the NP protein (S antigen).¹¹⁷ Antibody to NP protein develops first, 3 to 7 days after the onset of symptoms. Antibodies to NP protein are short lived and usually are absent after 6 months; they cross react with parainfluenza viruses. Antibodies to HN glycoprotein develop 2 to 4 weeks after the onset of illness and persist for long periods after infection.

Immunoglobulin (Ig) G and IgM antibody responses (determined by enzyme-linked immunosorbent assay [ELISA]) regularly occur after infection.²¹⁰ IgG antibody levels measured by ELISA correlate best with those derived by complement-fixation and hemolysis-in-gel assays. ELISA results are less specific than are those achieved with the plaque-reduction neutralization assay because of the high rate of cross-reacting antibodies against parainfluenza viruses detected by ELISA.^{145,172} IgM antibodies develop early in the course of infection (second day of illness), peak within the first week of illness, and usually are undetectable 3 months after the onset of illness; occasionally, mumps-specific IgM antibody persists for 5 to 6 months.^{117,210} Mumps-specific IgG antibody appears at the end of the first week of illness, peaks 3 weeks later, and persists throughout life. The IgG response is mainly the IgG1 subclass; a minor IgG3 subclass response also occurs.¹⁸⁷ Salivary IgA antibodies to mumps virus regularly appear after infection.⁷⁰

During infection with vaccine virus, the cell-mediated response to tuberculin is diminished for up to 4 weeks.¹²³ During the same period, a mumps-specific, cell-mediated immune response develops.^{117,227} This response has been demonstrated by skin test hypersensitivity, *in vitro*

lymphocyte proliferative responses, and cytotoxic T-lymphocyte studies.^{24,26,118} Asano and colleagues⁸ demonstrated a significant increase in interleukin (IL)–8, IL-10, IL-12, IL-13, and IFN- γ levels in sera from Japanese patients with mumps meningitis when compared with sera from other patients with viral meningitis, a finding suggesting a distinct immunologic response. More specifically, Wang and associates,²¹⁸ in a study of 960 patients with mumps in China, found that IL-6 and IFN- γ levels were predictive of meningitis or encephalitis when compared with uncomplicated mumps cases.

In general, immunity against recurrent disease has been thought to be lifelong. However, Gut and associates⁸² noted 26 patients with mumps who had a previous history of mumps and antibody response patterns suggestive of reinfection and not primary infection. Specifically, these patients had a rise in IgG but not IgM titers. In a study of mumps in 281 children, reinfection after a previous infection was noted in 9 children.¹⁸⁴

CLINICAL MANIFESTATIONS

In epidemics of mumps, cases can be separated into five groups of patients: (1) those with a short course whose signs and symptoms are nonspecific, (2) those in whom the disease is full blown with salivary swelling but no complications, (3) those with severe mumps and complications (epididymo-orchitis or meningoencephalitis, or both, or other complications), (4) those with no apparent symptoms but with typical antibody responses, and (5) those with meningoencephalitis or orchitis but without involvement of the salivary glands.²⁰¹ Approximately 75% of all cases of apparent mumps in children are of the full-blown type without complications. Involvement of the gonads rarely occurs before puberty.

Typical Mumps Without Complications

The average case in children has a prodromal period of 1 to 2 days that consists of fever, anorexia, headache, vomiting, and generalized aches and pains. The headache often is particularly marked and probably is caused by mild meningoencephalitis.⁶⁸ The temperature usually rises slowly to 38.9°C or 39.4°C (102°F or 103°F) as the disease becomes full blown, but at times fever is only slight or absent.²⁰¹

After the prodromal period, one or both parotid glands will begin to enlarge (Fig. 181.3). Mumps is bilateral in 70% to 80% of cases. A few days to a week or more may intervene between the swellings of the

FIG. 181.3 Note the swelling on the left side of the face related to parotitis secondary to mumps virus infection. The left ear protrudes from the side of the head.

two sides. A distinctive “puckering” sensation is experienced at the angle of the jaw in the early stage, and it may be increased by the application of sour liquids, such as lemon juice or vinegar, to the tongue. This sign, when present, may be useful for early establishment of the diagnosis. The swelling of the gland also is distinctive in that a brawny type of edema occurs about the parotid gland, the borders of which are not discrete, in contrast to the discrete swelling typical of lymphadenitis, in which the node generally is outlined easily. The lobe of the ear is in the center of the swelling, which usually cannot be separated by palpation from the angle of the mandible. Pressure is painful, and opening the jaw often is difficult.

The swelling of an individual gland reaches its maximum in approximately 3 days, remains at its peak for approximately 2 days, and then slowly recedes. The extent of the swelling varies considerably but at times is sufficient to distort the outline of the face and head completely. The submaxillary and sublingual glands may be involved separately or with the parotids in any combination.

During the prodromal phase, slight redness of the orifices of the Stensen or Wharton ducts, when present, has diagnostic significance. The amount of saliva usually is unchanged, although the mouth may be dry or salivation may be extreme. Gellis and Peters⁷⁴ described a few cases with edema over the upper part of the sternum, apparently caused by pressure on the lymphatics in the neck.

In uncomplicated mumps, the white blood cell count usually is low, with slight relative lymphocytosis. The serum amylase value typically is elevated.

Meningitis, Meningoencephalitis, and Encephalitis

Meningitis and mild meningoencephalitis are the most frequent complications of mumps in children. Azimi and colleagues¹¹ reviewed 51 children with mumps meningoencephalitis who were admitted to Columbus Children's Hospital in Columbus, Ohio, between July 1964 and December 1967. Of this group of patients, fever occurred in 94%, vomiting in 84%, nuchal rigidity in 71%, lethargy in 69%, parotid swelling in 47%, headache in 47%, convulsions in 18%, abdominal pain in 14%, sore throat in 8%, diarrhea in 8%, and delirium in 6%.

Clinical findings in neurologic illness caused by mumps virus infection differ according to the age of the patient. Meningeal signs are recognized more readily in older children, adolescents, and adults, whereas non-specific findings such as drowsiness and lethargy occur more frequently in young children.²²⁷ Although seizures develop in 20% to 30% of hospitalized patients, electroencephalographic results usually are normal. Even in patients with severe obtundation, the electroencephalogram reveals only diffuse slowing with increased voltage. Focal findings are rare. The outlook in mumps meningoencephalitis generally is good and usually is better than in encephalitis of other viral causes (see Chapter 36). Even patients with profound obtundation generally recover without having residual damage. Rarely, deaths do occur, however.³⁴

In the typical case, CSF has normal glucose and elevated protein levels and pleocytosis. Glucose levels are slightly low in approximately 20% of cases. At the onset of symptoms, modest mononuclear pleocytosis is present. The CSF cell count peaks on the third day of illness; counts average 250/mm³, but counts greater than 1000/mm³ are not uncommon. Mumps meningitis usually develops in patients with parotitis approximately 5 days after the onset of illness, but CNS findings can precede the parotid findings and can develop without any salivary gland involvement.

Herndon and colleagues⁹² noted that ependymitis regularly occurs in cases of mumps meningitis. A rare complication of mumps appears to be acquired aqueductal stenosis, and researchers have suggested that it may be caused by the preceding ependymitis.^{92,159,198,208} In one reported fatal case, hydrocephalus developed within 5 days of onset of disease.¹⁶² More recently, acute hydrocephalus associated with mumps meningoencephalitis was noted in an 8.5-year-old boy.⁶ This child received a ventriculoperitoneal shunt and at follow-up had no neurologic deficit.

A 3-year-old boy with mumps cerebellitis, nystagmus, and focal localization of brain lesions noted by electroencephalography was described.¹⁴² Also reported were facial palsy in a 3-year-old Japanese boy and transverse myelitis in an adult.^{60,213} A case in a girl 4 years and 3 months of age who had brainstem encephalitis and acute disseminated

encephalomyelitis after mumps has been reported.¹⁹⁶ This child responded rather dramatically to treatment with glucocorticoids and intravenous immunoglobulin. Haginoya and associates⁸⁴ reported the case of a 14-year-old Japanese girl who had chronic progressive mumps virus encephalitis. This child had an illness similar to subacute sclerosing panencephalitis, and her antibody titers suggested that the infecting virus may have had a defect in the HN protein.

Gonadal Infection (Epididymo-Orchitis and Oophoritis)

Epididymo-orchitis and oophoritis almost never occur before puberty.²⁰¹ However, in adolescent boys and adult men, epididymo-orchitis is second only to parotitis as a manifestation of mumps virus infection.¹¹⁹ Cases of orchitis have been reported in children as young as 3 years old.¹⁷⁶ In postpubertal male patients, orchitis develops in 30% to 38% with mumps.^{18,171} The rate of orchitis is highest in those 15 to 29 years of age. The greatest numbers of cases occur during the second, third, and fourth decades of life. Approximately 80% of cases of epididymo-orchitis appear during the first 8 days of involvement of the salivary gland, but a few cases occur a considerable time after the parotitis has subsided.²⁰¹

The onset of testicular involvement usually is manifested as chills, recurrence of fever, and swelling of the testes. Pain over the renal area or in the lower part of the abdomen, bilateral or unilateral, may precede or accompany the orchitis. Occasionally, this pain, if on the right side, may suggest appendicitis.

The orchitis usually is unilateral, but bilateral involvement has been reported in 17% to 38% of cases.^{18,171} Although atrophy may develop after orchitis, in patients with unilateral involvement, sterility is not a concern. Sterility has resulted after some cases of bilateral orchitis, however. A 16-year-old adolescent with mumps epididymo-orchitis was found to have persistent mumps virus RNA in his semen for 40 days.¹⁰⁴ In follow-up studies, he was found to have antisperm antibodies. The development of malignant disease in affected testes also has been reported.^{18,111}

Oophoritis occurs in approximately 7% of postpubertal female patients. Pelvic pain and tenderness are noted.¹⁸⁹

Pancreatitis

In a retrospective survey of 2482 hospitalized patients with mumps, pancreatitis was noted in 75 (3%).¹ Cases occurred in children and adults, and pancreatitis was 1.6 times more common in male than in female patients. Severe involvement of the pancreas is a rare occurrence, but mild or subclinical infection may occur more frequently than recognized.¹⁸⁹ It may be unassociated with salivary gland manifestations and be misdiagnosed as gastroenteritis. Epigastric pain and tenderness are suggestive; they may be accompanied by fever, chills, vomiting, and prostration. A child with acute hemorrhagic pancreatitis and a pseudocyst caused by mumps virus infection has been reported.⁶⁶

Diabetes Mellitus

Diabetes mellitus long has been suspected to be associated with antecedent mumps.^{31,87} In experimental animals, mumps virus infection has been linked to hyperglycemia and histologic lesions of the pancreatic islets. Mumps virus can invade the human pancreas and can infect and destroy human and rhesus beta cells in vitro,¹⁷⁵ but pancreatic damage has not been documented in reported cases of diabetes that developed after mumps or mumps vaccination.¹⁹⁵

In humans, many cases of temporal association have been described both in individuals and in siblings.^{52,53,116,149,158} and outbreaks of diabetes mellitus a few months or years after outbreaks of mumps have been reported.^{81,148,205} Although evidence has not established a causal association in these cases, a study in Surrey, England, suggested that a small proportion, if any, of diabetes cases that start in childhood (only 15 of the 1663 patients in the study [$<1\%$]) may have resulted from a recent mumps virus infection.⁷² Antibody studies have shown fewer positive titers for mumps in diabetic patients than in normal subjects, even in children.¹⁸⁵ Infection may contribute to the development of diabetes either by specifically damaging islet cells or by precipitating diabetes in patients whose disease is latent. Teng and colleagues²⁰⁷ reported the case of an 11-year-old girl with mumps infection complicated by transient hyperinsulinemic hypoglycemia.

Nephritis

Viruria is a common occurrence in uncomplicated mumps, and mild abnormalities in renal function occur.²¹¹ Severe and fatal nephritis was reported as a rare complication of mumps occurring 10 to 14 days after parotitis.¹⁸⁹ Fujieda and associates⁷¹ reported the demonstration of mumps virus genomic RNA by polymerase chain reaction (PCR) in a renal biopsy specimen from a 5-year-old girl with IgA nephropathy. Baas and colleagues¹² reported a case of a 56-year-old renal transplant recipient who developed acute irreversible transplant failure secondary to interstitial nephritis with mumps RNA detected in urine and renal biopsy.

Deafness

Deafness is an important but rare complication of mumps virus infection.^{29,77,120} Its incidence has been estimated at 0.5 to 5.0 per 100,000 cases of mumps.^{47,187} However, the incidence rate of minor degrees of hearing impairment, such as high-tone hearing loss, is probably much higher.⁴⁴

Mumps-associated deafness occurs with or without meningoencephalitis and may develop after asymptomatic infection.^{31,63,157} The deafness usually is unilateral and often permanent. Twenty-two of 103 cases (21%) reviewed by Everberg⁶³ were bilateral. Mumps virus has been isolated from perilymph fluid in a case of sudden-onset, unilateral, complete deafness that began 2 days after the onset of mumps.^{14,144} Vertigo also is noted occasionally in patients with mumps; it occurs most commonly in those in whom deafness develops.¹⁰³

Mumps and Pregnancy²⁴

The incidence of mumps during pregnancy was estimated at 0.8 to 10 cases per 10,000 pregnancies¹⁹⁰ before vaccine was licensed in the United States. No vaccine-era data are available for comparison. Maternal complications such as mastitis,¹⁷¹ aseptic meningitis,¹⁴ aseptic meningitis,²¹ and fatal glomerulonephritis⁵⁸ have been reported. Mumps virus has been isolated from human breast milk.¹¹³

Increased rates of fetal mortality were reported in women who contracted mumps during the first trimester. In a large prospective case-control study, a 27.3% rate of fetal wastage was noted in women with mumps during the first trimester versus a 13.0% rate in matched, healthy controls during the first trimester.¹⁹⁴ No significant differences in birth weight were noted among the live births.¹⁹³ Because fetal loss usually occurs in such cases within 2 weeks of development of maternal infection, investigators postulated that factors related to maternal gonadal infection with resulting hormonal changes may be responsible. A histopathologic study of the products of conception in mothers with gestational mumps revealed severe proliferative necrotic villitis and vasculitis in the placenta and viral inclusions, as seen in mumps infection, in fetal tissues.⁷³ Mumps virus was isolated from a spontaneously aborted 10-week-old human fetus.¹²⁵

No evidence has shown that gestational mumps in humans increases the risk of development of fetal malformations,¹⁹² although a few cases of various congenital malformations with no consistent pattern have been reported.⁹⁸

Other Manifestations

Other rare clinical manifestations include exanthem and enanthem,⁴³ arthritis,⁷⁸ myocarditis,¹⁹ thrombocytopenia,^{124,130,173} keratouveitis,¹⁶¹ lower respiratory tract infection,⁶⁹ and other glandular involvement (thyroiditis, mastitis, dacryoadenitis, and Bartholinitis).^{119,169}

DIFFERENTIAL DIAGNOSIS

Not all patients with mumps have parotid swelling, and mumps virus is not the only cause of parotitis. Mumps virus infection must be considered in all children with aseptic meningitis, meningoencephalitis, and encephalitis (see Chapters 35 and 36). In addition to mumps virus infection, many other infectious agents and noninfectious conditions are associated with parotitis or parotid swelling (see Chapter 13). Other viruses that can cause parotitis include Epstein-Barr virus, coxsackieviruses and echoviruses, influenza A virus, parainfluenza viruses, cytomegalovirus, human herpesvirus-6, and lymphocytic choriomeningitis

virus.^{15,27,55} Purulent parotitis can be differentiated from mumps by the exquisite tenderness of the region, an elevated white blood cell count, and the observation of pus coming from the Stensen duct. Other viral causes of parotitis can be differentiated by the respective epidemiologic and clinical characteristics of specific agents and appropriate culture, serologic study, or both.

Enlargement of lymph nodes in proximity to the parotid gland must be differentiated from parotid enlargement (see Chapter 12). The cervical lymph nodes are below the ramus of the mandible. The preauricular lymph nodes generally are anterior to the parotid, and their enlargement usually is associated with conjunctivitis. Occasionally, an enlarged lymph node within the parotid gland may cause some confusion. Lesions of the ramus of the mandible, such as osteomyelitis, occasionally have been mistaken for parotid enlargement. In this case, the enlargement usually is persistent.

DIAGNOSIS

In an epidemic situation, the diagnosis of mumps is clinically straightforward, and performing laboratory tests is unnecessary. The critical points are a history of exposure, an incubation period of 2 to 3 weeks, and a typical clinical picture consisting of fever and parotitis. In a sporadic case or in a previously vaccinated child, confirming the cause by laboratory study is important. Mumps virus, as well as most other viruses that cause parotitis, can be demonstrated readily by culture or nucleic acid detection from saliva, throat swabs, or mouth washings during acute illness. Oral fluid specimens can also be assayed for virus-specific IgM. In patients with meningoencephalitis, virus also can be recovered from CSF. Virus is isolated in primary monkey kidney tissue culture. In unusual cases in which the source of facial swelling is obscure, determination of a serum amylase level may be helpful; a high value indicates parotid involvement.

Mumps virus infection also can be confirmed by demonstrating a significant rise in antibody titer in paired serum specimens by complement fixation, hemagglutination inhibition, or ELISA. However, because mumps cross reacts with parainfluenza viruses, these methods are not ideal.¹⁷² Mumps-specific IgM antibody determined by ELISA is the usual test performed; the presence of this antibody indicates a recent infection. Mumps-specific IgM antibodies determined by enzyme immunoassay in oral fluid also are useful for establishing the diagnosis.²¹⁹ Mumps virus RNA also can be detected directly from clinical samples by real-time PCR.²⁰⁹ In outbreaks today, many cases occur in previously vaccinated individuals. Many of these vaccine failures are secondary and, therefore, there is less likely to be a mumps-specific serum IgM antibody response.^{134,179} Therefore, greater diagnostic sensitivity will occur when using culture or PCR assay. In the 2009 to 2010 New York mumps outbreak, an increase in sensitivity with either method was noted after 2 to 3 days of symptoms.¹⁷⁷

TREATMENT

Conservative therapy is indicated in the treatment of mumps. Adequate attention given to hydration and alimentation of patients is important. Patients may have difficulty with acidic foods such as orange juice. In addition, orange juice may cause vomiting in an already nauseated patient. The diet should be light, with a generous offering of fluids.

Occasionally, analgesics are necessary to treat severe headache or discomfort caused by parotitis. Stronger analgesics such as codeine or meperidine (Demerol) rarely are required for headache but may be useful for orchitis. Vomiting seldom is sufficiently severe to require intravenous fluids. In these instances, however, electrolytes lost by vomiting should be replaced.

Although lumbar puncture seldom is necessary for establishing a diagnosis in patients with meningoencephalitis accompanying mumps, patients often indicate that they have experienced relief of headache after undergoing this procedure. No antiviral agent is appropriate or indicated for the treatment of mumps, which is a self-limited illness. Systemic reviews of the literature failed to identify useful information regarding the utility of traditional Chinese medicine or acupuncture for the treatment of mumps.^{89,191}

A potential new treatment for mumps orchitis specifically is IFN- α 2b. In a small study of 12 patients, both symptom resolution and normospermia were improved versus results in untreated control subjects.^{62,121}

PROGNOSIS

The overall prognosis in uncomplicated mumps is excellent. The outlook in meningoencephalitis also generally is favorable, but death and neurologic damage can occur. Deafness and sterility are rare complications.

PREVENTION

Immunization

Numerous different mumps vaccines are available in different countries throughout the world.¹⁸² These vaccines have different effectiveness and reactogenicity profiles. In this chapter, recommendations relating to the vaccines available in the United States are presented.

A summary of the recommendations of the Advisory Committee on Immunization Practices (ACIP) and the Committee on Infectious Diseases of the American Academy of Pediatrics for the use of mumps vaccine follows.^{7,40} For more complete information, the reader should consult the most recent ACIP statement or the Report of the Committee on Infectious Diseases of the American Academy of Pediatrics.

The mumps virus vaccine available in the United States (official name: mumps virus vaccine, live) is the Jeryl Lynn strain and is prepared in chick embryo cell culture. The vaccine produces a subclinical, noncommunicable infection with few side effects. Mumps vaccine is available in the following combinations: MMR and measles-mumps-rubella-varicella (MMRV) vaccines.

In initial trials, mumps vaccine had an approximately 95% effectiveness in preventing mumps disease^{95,114,203}; and after vaccination, measurable antibody developed in more than 97% of persons known to be susceptible to mumps.²²³ Vaccine-induced antibody was protective and long lasting,^{221,222} although it was of considerably lower titer than antibody resulting from natural infection.²²³ The duration of vaccine-induced immunity is unknown, but serologic and epidemiologic data collected during 35 years of use of live vaccine suggested both persistence of antibody and continuing protection against infection. The epidemic occurrence of mumps in 2006 in the United States and in other countries resulted in further evaluations of vaccine efficacy and waning immunity.^{24,40,48,88,109,168,212} In a study in England, the effectiveness of vaccine after one dose declined from 96% in 2-year-old children to 66% in children 11 to 12 years old.⁴⁸ In the 2010 to 2001 outbreak in Germany, a very small sampling ($n = 20$) revealed poor (50%) vaccine effectiveness in young adults given one dose in childhood and good protection with no evidence of waning if two doses had been administered.²⁰⁶ In those children who had received two doses, the effectiveness declined from 99% in children 5 to 6 years old to 86% in children 11 to 12 years old. These data suggest that waning immunity contributes to outbreaks of mumps in older, previously vaccinated populations. Studies in Belgium and Korea also demonstrated waning immunity as contributing to outbreaks of mumps.⁴² However, a small study in Wisconsin compared the mumps antibody titers of children who received their second MMR shot at age 4 to 6 years (as is typical) with delaying until age 9 to 11 years. At age 17 years, both groups had similar titers.¹³⁵

In Finland, a two-dose MMR vaccination program with the Jeryl Lynn mumps vaccine strain was launched in 1982.¹⁷⁰ This program was highly successful, and Finland was the first country documented to be free of indigenous mumps, as well as rubella and measles. In a study in Finland that was published in 2007, researchers found that previous vaccinees who were found to be seronegative nonetheless had mumps antigen-specific lymphoproliferative responses.¹⁰⁹

In a review of 47 publications documenting the vaccination status of patients during 50 outbreaks from 1977 through 2008, Dayan and Rubin⁵⁷ calculated that the effectiveness of prior vaccination with one dose of vaccine ranged from 72.8% to 91% for the Jeryl Lynn strain, from 54.4% to 93% for the Urabe strain, and from 0% to 33% for the Rubini strain. Vaccine effectiveness after two doses of mumps vaccine was reported in three outbreaks and ranged from 91% to 94.6%.¹⁸¹ In the 2009 to 2010 New York outbreak, two-dose effectiveness was 86.3%.¹⁴⁰

Clinical isolates sequenced from recent outbreaks have revealed genotypes distinct from those of vaccine viruses, thus raising concern that certain mumps virus strains may escape vaccine-induced immunity. Rubin and colleagues¹⁸¹ performed a study in which sera obtained from children 6 weeks after MMR vaccination were tested for the ability to neutralize genetically diverse mumps virus strains. Although antibody titers varied, all viruses were readily neutralized, arguing against immune escape.

An immunoinformatic analysis performed by a private laboratory in Wisconsin in 2014 revealed significant differences in the CD4⁺ helper T cells elicited by wild-type and vaccine response, and the investigators postulated that vaccine efficacy with the original strains (including JL5) may have overemphasized vaccine efficacy as a result of frequent wild-type boosting that overcame a potential lack of appropriate T-helper stimulation from exposure to the JL5 vaccine strain.⁹⁹ These investigators concluded that serologic methods to evaluate vaccine efficacy and immunity may have overemphasized the conservation of one neutralizing epitope at the expense of others that could more accurately predict amnestic responses.

The vaccination rates in the United States in 1999 through 2004 were 90%, which is at the low end of the estimated population immunity (90–92%) needed for herd immunity.¹²⁶ It appears that outbreaks have occurred when vaccination rates drop below that required for herd immunity, and both vaccinated and unvaccinated individuals are at risk of infection. At present, the contribution of waning immunity to outbreaks is not well understood, and additional booster vaccinations are not routinely recommended in nonoutbreak settings. Notably, the 2006 Midwestern US outbreak and the 2009 to 2010 New York outbreak occurred in the setting of very high two-dose vaccine coverage, thereby leading to the suggestion that a more effective vaccine or an updated vaccination policy was needed.^{56,128} Additional outbreak reports worldwide corroborate that high vaccination coverage is not necessarily protective.^{22,75,80,131,141,143} Analysis of the seroepidemiology of mumps in 18 European countries between 1996 and 2008 suggests that in endemic-prone areas, repeating vaccination every 4 to 8 years is a potential strategy to prevent outbreaks.⁶¹ Abrams and colleagues⁴ described a computer-based mathematical model to estimate the risk of a mumps outbreak in highly vaccinated population by using spatial seroprevalence data.

A 2014 phase I clinical trial of a new F-genotype live attenuated mumps vaccine in China suggested adequate safety and effective immunogenicity.¹³⁸

General Recommendations

Susceptible children, adolescents, and adults should be vaccinated against mumps unless vaccination is contraindicated. Mumps vaccine is of particular value for children approaching puberty and for adolescents and adults who have not had mumps. MMR and MMRV are the vaccines of choice for routine administration and should be used in all situations in which recipients also are likely to be susceptible to measles, rubella, or varicella. Persons should be considered susceptible to mumps unless they have documentation of (1) physician-diagnosed mumps, (2) two doses of live mumps virus vaccine with the first dose on or after their first birthday, or (3) laboratory evidence of immunity.

Persons who are unsure of their history of mumps disease or mumps vaccination should be vaccinated. No evidence has shown that persons who previously either received mumps vaccine or had mumps are at any increased risk for developing local or systemic reactions from receiving live mumps vaccine. Testing for susceptibility before administering vaccination, especially in adolescents and young adults, is not necessary.

Dosage

Two doses of MMR vaccine separated by at least 1 month in the volume specified by the manufacturer should be administered subcutaneously.

Age

Live mumps virus vaccine is recommended at any age on or after the first birthday for all susceptible persons, unless a contraindication exists. In routine circumstances, mumps vaccine should be given as MMR or MMRV, and the currently recommended schedule for administration

of measles vaccine should be followed. It should generally not be administered to infants younger than 12 months old because persisting maternal antibody may interfere with seroconversion. To ensure that the patient has developed immunity, all persons vaccinated before their first birthday should be revaccinated on or after their first birthday.

Persons Exposed to Mumps

Use of Vaccine

When given after exposure to mumps, live mumps virus vaccine may not provide protection; although in a small cohort, it showed some promise when given as postexposure prophylaxis in the 2009 to 2010 New York outbreak.⁶⁷ However, if the exposure did not result in infection, vaccine should induce protection against infection from subsequent exposure. No evidence has indicated that the risk of vaccine-associated adverse events increases if vaccine is administered to persons incubating disease. In the 2009 to 2012 outbreak in New York, eligible 6th- to 12th-grade students were offered a third MMR vaccine, with a dramatic decline in incidence shortly after the intervention.¹⁶⁰ A lower rate of adverse events (with no serious events) was also observed, and it was concluded that a third dose of MMR vaccine may be effective in controlling future outbreaks.³ In the 2009 to 2010 Guam outbreak in a cohort of 1068 students with two-dose coverage, there was a trend toward protection with a prophylactic third dose, and no serious adverse events were reported.¹⁵⁵

Use of Immunoglobulin

Immunoglobulin has not been demonstrated to be of established value in postexposure prophylaxis and is not recommended.

Adverse Effects of Vaccine Use

In field trials in the United States before vaccine was licensed, illnesses did not occur more often in vaccinees than in unvaccinated control subjects.⁹⁴ Reports of illnesses occurring after receipt of mumps vaccination have been episodes mainly of parotitis and low-grade fever. Allergic reactions, including rash, pruritus, and purpura, have been associated temporally with mumps vaccination but are uncommon and usually mild and of brief duration. The reported development of encephalitis within 30 days of receiving a mumps-containing vaccine in the United States (0.4 per million doses) is not greater than the observed background incidence rate of CNS dysfunction in the normal population. Other manifestations of CNS involvement in the United States, such as febrile seizures and deafness, also have been reported infrequently. Complete recovery usually occurs. Reports of nervous system illness occurring after receipt of mumps vaccination do not necessarily denote an etiologic relationship between the illness and the vaccine. In parts of Europe, Canada, and Japan, where different mumps vaccines (Leningrad 3 strain and Urabe Am 9 strain) have been used, rates of vaccine-induced aseptic meningitis have been high.^{45,49,146,153,204} Orchitis is a very rare complication of mumps vaccination.⁴⁶ Most cases have occurred in adolescents and adults, and five different vaccine strains have been associated with orchitis.

Contraindications to Vaccine Use

Pregnancy

Although mumps vaccine virus has been shown to infect the placenta and fetus,²²⁹ no evidence has indicated that it causes congenital malformations in humans. However, because of the theoretic risk of fetal damage, a prudent approach is to avoid giving live virus vaccine to pregnant women. Women should avoid becoming pregnant for 3 months after receiving vaccination. Routine precautions for vaccinating postpubertal women include asking whether they are or may be pregnant, excluding those women who say that they are, and explaining the theoretic risk to those who plan to receive the vaccine. Being vaccinated during pregnancy should not be considered an indication for termination of pregnancy. However, the final decision about interruption of pregnancy must rest with the individual patient and her physician.

Severe Febrile Illness

Administration of vaccine should not be postponed because of minor or intercurrent febrile illnesses such as mild upper respiratory tract

infections. However, vaccination of persons with severe febrile illnesses generally should be deferred until they have recovered.

Allergies

Because live mumps vaccine is produced in chick embryo cell culture, persons with a history of anaphylactic reactions (e.g., hives, swelling of the mouth and throat, difficulty breathing, hypotension, shock) after ingesting eggs should be vaccinated only with caution and according to published protocols.^{79,91} Children known to be allergic should not leave the vaccination site for 20 minutes after being vaccinated. Evidence indicates that persons are not at increased risk if they have egg allergies that are not anaphylactic. Such persons may be vaccinated in the usual manner. No evidence has demonstrated that persons with allergies to chickens or feathers are at increased risk of having a reaction to the vaccine.

Because mumps vaccine contains trace amounts of neomycin (25 µg), persons who have experienced anaphylactic reactions to topically or systemically administered neomycin should not receive mumps vaccine. Most often, allergy to neomycin is manifested as contact dermatitis, which is a delayed-type (cell-mediated) immune response rather than anaphylaxis. In such persons, the adverse reaction, if any, to 25 µg of neomycin in the vaccine would be an erythematous, pruritic nodule or papule at 48 to 96 hours. A history of contact dermatitis to neomycin is not a contraindication to receiving mumps vaccine. Live mumps virus vaccine does not contain penicillin.

Recent Immunoglobulin Injection

Passively acquired antibody can interfere with the response to live attenuated virus vaccines. Therefore, mumps vaccine should be given at least 2 weeks before the administration of immunoglobulin or be deferred for 3 to 11 months after the administration of immunoglobulin. The duration of deferral depends on the dose of immunoglobulin administered.²²⁰

Altered Immunity

In theory, replication of the mumps vaccine virus may be potentiated in patients with immunodeficiency disease and by the suppressed immune responses that occur with leukemia, lymphoma, or generalized malignancy or with therapy with corticosteroids, alkylating drugs, antimetabolites, or radiation. In general, patients with such conditions should not be given live mumps virus vaccine. Because vaccinated persons in the United States do not transmit mumps vaccine virus, the risk of exposure to mumps in these patients may be reduced by vaccinating their close susceptible contacts. Interestingly, a handful of cases of horizontal transmission have been reported in Belarus and Croatia, all associated with the Leningrad-Zagreb or Leningrad-3 MuV virus strains.^{9,10,110,165}

An exception to these general recommendations is in children infected with human immunodeficiency virus (HIV): all asymptomatic HIV-infected children should receive MMR vaccine at 12 months of age.^{32,220} If measles vaccine is administered to symptomatic HIV-infected children, the combination MMR vaccine generally is preferred.³³

Patients with leukemia in remission whose chemotherapy has been terminated for at least 3 months also may receive live mumps virus vaccine. Short-term (<2 weeks' duration) corticosteroid therapy, topical corticosteroid therapy (e.g., nasal, skin), and intraarticular, bursal, or tendon injections with corticosteroids are not contraindications to the administration of mumps vaccine. However, mumps vaccine should be avoided if systemic immunosuppressive levels are reached by prolonged, extensive, topical application.

Live vaccines have historically been avoided in patients who have received bone marrow, stem cell, and solid-organ transplantation. An international consensus conference recommends two doses of the MMR vaccine for allogeneic hematopoietic stem cell transplant recipients starting 24 months after transplant and once they are no longer receiving immunosuppressive therapy.⁹³ A review by Danerseau and Robinson in 2008⁵⁴ concluded that there were insufficient published data to determine the safety and/or efficacy of live viral vaccines in transplant recipients still receiving immunosuppressive therapy.

Containment of Disease

Containment is important in prevention of mumps in the United States. Mumps is a reportable disease, and compliance is the obligation of all

physicians. After early reports of sporadic mumps cases, health department workers can organize local immunization clinics and exclude susceptible students from school so that disease can be contained in a small geographic area. Kutty and colleagues¹²⁷ published a discussion of containment strategies in wake of the 2006 US outbreak. Isolation of case patients was the primary outbreak control measure.

A 2008 CDC update recommended isolation of infected persons for 5 days after onset of parotitis and for contact and droplet precautions during this time.⁴⁰ These recommendations were based on data from the 2006 Iowa outbreaks, which yielded information on the duration of virus shedding after symptom onset,¹⁷⁴ as well as poor compliance with 9-day as compared with 5-day isolation regimens.¹⁹⁷

Respiratory syncytial virus (RSV) is the most important respiratory pathogen of infancy and early childhood and the major cause of hospitalization for bronchiolitis and pneumonia in infants globally.^{39,101-103,152,225,228} In the United States, RSV has been estimated to be the leading cause of all hospitalizations for infants, resulting in an estimated 74,000 to 126,000 hospitalizations each year from 1994 to 1996.^{175,250} More recent studies suggest that these figures are lower than the current number of infant hospitalizations associated with RSV infections and that the associated annual costs are approximately \$2.6 billion.^{131,133,145} Furthermore, the considerable burden of RSV infections among older children, adults, and outpatients has not been recognized. It is estimated that more than 2 million children younger than 5 years require outpatient management annually because of RSV infection, and 2% to 3% require hospitalization in the United States.^{102,103,131} The situation is worse in developing countries, where it is estimated that RSV may cause 66,000 to 199,000 deaths annually.^{25,208} In contrast, fewer than 100 deaths occur annually in the United States, and death rates are declining.⁴⁴ Overall, little doubt exists that the worldwide burden of lower respiratory tract disease attributable to RSV exceeds that of *Haemophilus influenzae* type b and *Streptococcus pneumoniae*.²¹⁵ The annual rate of hospitalizations caused by RSV, compared with that for influenza or the parainfluenza viruses, has been approximately three times greater for children aged 5 years and younger and six to eight times greater for children younger than 1 year. Adding to this burden of disease are emergency department and pediatric office visits, which occur at 5 to 10 times the rates of hospitalization.^{71,72,91,112}

Among previously healthy working adults between 18 and 60 years of age, more than one-third require time away from work or school because of RSV infection. Among adults older than 65 years, RSV is a common cause of both upper and lower respiratory tract disease. Among elderly people, RSV-related deaths in the United States are estimated to exceed 10,000 annually; those with cardiopulmonary comorbidities are at greatest risk.^{49,50,86,88}

RSV is marked by its contagiousness and by its propensity to cause the most severe disease during the first few months of life, despite the uniform presence of specific maternal antibody. Sizable outbreaks occur each year, with the result that most children become infected at least once in their first 2 years of life.^{104,105,131} Nearly all first infections are symptomatic, and 20% to 30% involve the lower respiratory tract.^{99,102,104,105} Reinfections occur throughout life despite an absence of major antigenic changes in viral surface proteins and commonly are sufficiently symptomatic to cause absence from work or school.^{103,127}

HISTORY

In 1956, Morris and associates²⁰² noted an outbreak of colds with coryza in a colony of chimpanzees that had been under observation for the previous 3 to 24 weeks. A new virus was recovered from 1 of the 14 afflicted chimpanzees, and it was appropriately named chimpanzee coryza agent (CCA). Specific antibody to the CCA agent developed in the remaining 13 animals during convalescence; thus the attack rate was 100%. An upper respiratory tract infection and a serologic antibody response to CCA also developed in a person working with these chimpanzees, but the virus was not isolated from his secretions. However, further evidence of the pathogenicity of CCA was obtained subsequently when the CCA virus isolated from one chimpanzee was inoculated into susceptible chimpanzees and a coryzal illness developed after 3 days.

The suspected human origin of the chimpanzee coryza agent was confirmed a year later when Chanock and Finberg⁵⁴ recovered two agents indistinguishable from the CCA virus from the throat swabs of an infant with bronchopneumonia (Long strain) and from a child with laryngotracheobronchitis (Snyder strain). These investigators also observed an antibody response to these viruses in patients with respiratory disease and noted that by the time they reached 4 years of age, 80% of children had neutralizing antibody against the Long strain. Nonetheless, these investigators could not determine a definite etiologic association between the virus and lower respiratory tract disease in their young patients. They proposed naming this group of viruses (Long, Snyder, and CCA) respiratory syncytial virus because of their similar clinical manifestations and striking viral cytopathic effect of syncytial formation and multinucleated giant cells when the virus was grown in vitro. Confirmation of RSV as a major agent of respiratory disease soon accumulated from studies throughout the United States, and investigators from many countries subsequently documented and further delineated the importance of RSV.²⁵

STRUCTURAL AND ANTIGENIC PROPERTIES

and outer quill...*

—C.B.H.

Classification

The original classification of RSV with the Newcastle disease and parainfluenza group of viruses was based on their similar internal particle structure, eosinophilic inclusions, and syncytial appearance in tissue culture. However, RSV is antigenically distinct and does not hemagglutinate erythrocytes. Subsequently, the diameter of the nucleocapsid of RSV was determined to be between that of the larger paramyxoviruses and that of the smaller influenza viruses. Further study of the structure of RSV resulted in its current classification in the order Mononegavirales, family Paramyxoviridae, subfamily Pneumovirinae, and genus *Pneumovirus*.⁶⁴ RSV belongs, along with pneumonia virus of mice, bovine RSV, ovine RSV, caprine RSV, and turkey rhinotracheitis virus, to the subfamily Pneumovirinae, which consists of two genera, *Pneumovirus* and *Metapneumovirus* (MPV). The second genus, *Metapneumovirus*, contains human metapneumovirus (hMPV).⁶⁴

Structural and Antigenic Properties

The virion of RSV consists of a nucleocapsid enclosed within an envelope consisting of a bilipid layer derived from the plasma membrane of host cells. Transmembrane glycoprotein spikes on its surface give the virus the appearance of a thistle on electron microscopy. The genome of RSV (strain A2) has been completely sequenced and is composed of 15,222 nucleotides. It is a nonsegmented, single-stranded, negative-sense RNA genome that encodes 11 proteins. Each of the major messenger RNAs (mRNAs) (Fig. 182.1) encodes for one of the major proteins, except for M2 mRNA, which possesses two overlapping open reading frames that encode for two separate proteins (M2-1 and M2-2).^{64,295} Eight of these, including the seven largest (L, G, F, N, P, M, and SH), are structural proteins; two (NS1 and NS2) are nonstructural proteins that interfere with the interferon type I and type III response; M2-1 and M2-2 proteins are involved in RNA synthesis.¹⁹⁹

Of the structural proteins, three form the viral capsid: N (nucleo-protein), P (phosphoprotein), and L (polymerase). Two are matrix

membrane-associated proteins: the nonglycosylated M and M2 (the transcriptional antiterminator protein or transcriptase processivity factor, M2-1). The other three structural proteins, the glycosylated F (fusion) and G (attachment) proteins and the small, nonglycosylated hydrophobic SH protein, are transmembrane surface proteins.⁶⁴ The larger M protein is responsible for reassembly of the virus after it has entered a target cell and synthesized all of its proteins.¹⁹⁹ The F and G proteins are integral to RSV's infectivity and pathogenicity. The primary function of G, the largest glycoprotein, appears to be in the initial attachment of the virus to the host cell and is unusual compared with the attachment proteins of other paramyxoviruses because it has no hemagglutinin or neuraminidase. Initial penetration of the virus then is mediated by the F protein by fusing the viral and host cellular membranes, a process that allows cell-to-cell spread of the virus and results in the syncytia characteristic of RSV. However, all three of the surface glycoproteins, F, G, and SH, appear to act in concert to enhance the fusion process. Binding to a cellular receptor produces conformational changes in the F protein resulting in fusion of the virion envelope with the membrane of the cell.¹⁹⁶ Previously, G protein was identified as the major attachment protein, but more recently the F protein also has been recognized as having an important role in attachment of the virus.²⁶³

Significant strain variations among RSV isolates cause strains to be divided into two major groups.^{13,295} These two major groups, A and B, have intergroup and intragroup variations in several proteins, including F, G, P, and N. The primary differences reside in the largest surface glycoprotein, the G protein. The amino acid sequence of the G protein varies by approximately 50% between the RSV A and RSV B strain groups. Intragroup strain variation also occurs mainly within the G protein. In contrast, within F protein, the amino acid sequence is conserved relatively well, and thus neutralizing antibody to F protein is cross-reactive between the two strain groups.⁶⁴ The F proteins of prototype strains from groups A and B have greater than 90% amino acid homology and a high degree of antigenic relatedness.

Laboratory Growth

RSV is relatively labile and is destroyed rapidly at 55°C. At 37°C, infectivity does not diminish for 1 hour, but by 24 hours, only 10% remains. RSV can grow in a variety of human and animal cell cultures. Human heteroploid cells, such as HEp-2, HeLa, and A549 cells, are used most frequently for primary isolation. Additional cell cultures that may be used, but generally are less sensitive, include diploid fibroblastic, monkey kidney, human kidney, and amnion cells. However, the sensitivity of these cell lines is variable, especially with passage, and must be monitored constantly. The characteristic cytopathic effect of RSV in continuous cell lines is syncytial formation with eosinophilic cytoplasmic inclusions. The syncytia usually are evident 2 to 7 days after inoculation and progress to complete degeneration within about 4 days.^{64,120} The cytopathic effect, however, depends on the strain of virus, the medium, the sensitivity and thickness of the cell cultures, and the number of passages. Syncytia tend to be less evident in fibroblast cell lines; and in some primary cell cultures, RSV may produce rounded, refractile cells.

The growth cycle of RSV has been shown to consist of a period of adsorption, in which 50% of the inoculum is adsorbed in 2 hours, followed by an eclipse period of 12 hours. New virus appears shortly thereafter and enters a log phase of replication lasting approximately 10 hours. Viral antigen can be documented by fluorescent antibody staining 7 to 10 hours after inoculation. Shortly thereafter, cell-free virus may be demonstrated in the culture medium, but 50% to 90% of the virus remains associated with the cell surface at the time maximal titers are reached. Most of the cell-associated virus consists of incomplete noninfectious virions that may be released by agitation and sonication. With the laboratory Long strain (group A), peak titers usually are reached in 48 hours. For each infected cell, approximately 10 plaque-forming units generally result. Titers of virus are enhanced by inoculation of cell monolayers that are not yet confluent.⁶⁴

Animal Susceptibility

An animal model of human RSV disease is a critical step in the search for effective antiviral therapy as well as for development of a vaccine. The natural hosts for symptomatic RSV infection are primarily humans and chimpanzees. Susceptible animals that could serve as a model for the lower respiratory tract disease of infants have been sought for some time.^{20,82} Although RSV grows in the lung of a variety of animals, direct inoculation into their respiratory tract generally produces infection that is clinically and pathologically silent. Cattle are naturally infected with bovine, but not human, RSV.⁸² RSV also has been recovered from asymptomatic goats and sheep. Other domestic animals, such as dogs and cats, have been found to possess antibody to RSV, the significance of which is unclear.

Chimpanzees resemble humans in some aspects in their clinical response to RSV, in that they develop rhinorrhea with natural RSV infection, and may transmit the virus to others of their species. Histologic pneumonia and some degree of clinical disease have been induced in many other adult primates, but the illness is mild in nature.^{20,82} Infant baboons, however, develop tachypnea and reduced oxygenation following infection with RSV, with interstitial pneumonia, bronchiolitis, and obstruction of bronchiolar airways with inflammatory and sloughed epithelial cells similar to that observed in human infants. Fatal bronchiolitis can occur in infant baboons challenged with RSV. As in human infants, CD8 lymphocyte responses are absent with severe disease in infant baboons.²²¹ Infection in cattle can result in lung disease, but secondary bacterial infection may be required for symptoms to be evident. Marked lung pathology can be observed in sheep infected with RSV, but infection remains asymptomatic.⁴⁵ Infection in ferrets is age dependent, with limited histopathologic features developing in the nasal turbinates and trachea (but not lung) of adults. In infant ferrets, however, the virus replicates in the lung, although symptomatic respiratory disease is not apparent. RSV replicates in cotton rats better than in most animal models.²³¹ With intranasal inoculation, viral titers peak in the lung and nasal turbinates after 4 to 5 days. Illness is not apparent clinically, however. Histologic changes in the lung are present but are inconsistent, and immunologic reagents are limited compared with those for mice. Replication of RSV in other rodents generally is limited. BALB/c mice are among the most susceptible, and marked pulmonary disease may occur with high-titer inocula, which in older mice is accompanied by tachypnea and evidence of airway obstruction.²⁷⁶ Disease in these mice, however, is mediated by aggressive CD4 and CD8 lymphocyte responses, which is the opposite of what occurs in humans, where CD8 responses are absent in infants with fatal disease.^{113,292}

A human model of RSV infection has been reported in which healthy adult volunteers are infected intranasally with an attenuated strain of RSV and observed for viral load, immune markers, and clinical symptoms.⁷⁶⁻⁷⁸ It is hoped that the availability of a safe and reproducible human model will permit more rapid testing of novel drugs and immunotherapies.

EPIDEMIOLOGY

*What occult power pries loose the lid
 to give you winter flight,
 But with the lengthening light of spring
 gives cloak and leaden wing?*

—C.B.H.

TABLE 182.1 Summary of Median Values of Respiratory Syncytial Virus Season Characteristics for Entire Nation and US Census Regions From National Respiratory and Enteric Virus Surveillance System Data, 1990–2000

Location	MEDIAN WEEKS OF YEAR FOR RSV			
	Onset	Peak	Offset	Duration
Nation	51 (late December) ^a	5 (early February)	13 (end of March)	15
West	52 (late December)	6 (mid February)	13 (end of March)	14
Midwest	1 ^b (early January)	7 (late February)	13 (end of March)	13 ^b
South	47 ^c (late November)	1 (early January)	10 (mid March)	16 ^b
Northeast	49 (early December)	4 (end of January)	12 (late March)	15

^aNumbers in parentheses, time of year.
^bStatistically different from the rest of the nation, $P < .05$.
^cStatistically different from the rest of the nation, $P < .01$.
From Mullins JA, LaMonte AC, Bresee JS, Anderson LJ. Substantial variability in community respiratory syncytial virus season timing. *Pediatr Infect Dis J*. 2003;22:857-862.

Geographic Distribution

Infection with RSV occurs worldwide, with its predominant pathogenicity occurring in the very young, in elderly people, and in those in each of those age groups who have underlying high-risk conditions, largely heart and lung disease. All geographic areas of the world experience RSV activity in every year. The timing, length, and intensity of RSV outbreaks, however, vary geographically.

Seasonal Patterns

In temperate locations, community outbreaks generally occur during the cold season. Outbreaks in warm and tropical climates tend to be more prolonged, with essentially continuous activity.^{89,97} Within the United States, the inevitability of the RSV season is predictable, but the severity of the season, the time of onset, the peak of activity, and the end of the season cannot be predicted with precision (Table 182.1). The timing of RSV outbreaks often shows variation from year to year within the same community. This variation, however, occurs within the overall pattern of RSV seasonality in temperate climates, with epidemic activity generally beginning in November or December, peaking in January or February, and ending in March or April. Trends in RSV seasonality are monitored by the National Respiratory and Enteric Virus Surveillance System maintained by the Centers for Disease Control and Prevention.^{49,50} Communities in the southern states tend to experience the earliest onset of RSV activity, and those in the upper Midwest tend to experience the latest onset. The duration of the season for the western and northeast regions typically occurs between that observed in the South and the Midwest. During the four RSV seasons of 2007 through 2011, the seasonal onset occurred from mid-November to early January, and the season's end occurred from mid-March to late April across all 10 Department of Health and Human Services regions. The median duration ranged from 13 to 23 weeks, and the peak of RSV activity occurred from mid-December to early February.^{49,50} In regions where the season begins in November or December, the season ended by April or early May. In the few areas where the RSV season began in October, the season ended in March or early April. Florida is reported separately because, in some parts of the state, there is an earlier onset and earlier end to RSV circulation than the rest of the United States. Southeastern Florida (Miami area) has continuous RSV activity throughout the year.^{49,183} Regional differences in RSV activity probably have a multifactorial explanation, including temperature, humidity, ultraviolet light exposure, social behavior, and probably other factors.^{90,221,284} Areas near the equator and those in extremely cold climates have nearly continuous activity.³⁰⁷ In contrast to data from the Western Hemisphere, where epidemic peaks occur annually in January and February, RSV activity in central Europe occurs in a biennial cycle, with peaks alternating between January and February in one year and between March and April in the following year.¹⁵¹ The number of RSV infections causing hospitalization correlates with RSV activity in the community (Fig. 182.2).^{49,183,250}

Specific groups of American Indian/Alaska Native children in certain geographic areas (particularly young children in southwestern Alaska)

FIG. 182.2 The number of cases of bronchiolitis and the number of isolates of respiratory syncytial virus (RSV) from children younger than 5 years who were evaluated in private offices and outpatient facilities from 2000–05 identified by a community surveillance program in Monroe County, NY.

may experience more severe RSV disease and a longer RSV season than those in other parts of the United States.²⁵⁴ Navajo and White Mountain Apache infants and young children may experience RSV hospitalization rates that are two to three times those of similar-aged children in other parts of the country.^{43,215}

In geographic regions with temperate climates, including both the Northern and Southern Hemispheres, periods of RSV activity correlate with cold weather. In equatorial countries, RSV activity continues for much of the year. These patterns suggest the possibility that meteorologic conditions influence the dissemination of virus. Efforts have been made to correlate RSV activity in different geographic locations with mean daily temperature, dew point, absolute humidity, ultraviolet B radiance, relative humidity, and precipitation. Results show a complex interaction between RSV circulation and environmental conditions that cannot be correlated easily.^{92,288,291} In addition, weather conditions are likely to alter behavior, such that colder temperatures and rainy weather result in more time spent indoors, resulting in closer contact with other individuals and facilitating the spread of virus.

Results from several epidemiologic studies suggest that vitamin D may be protective against RSV lower respiratory tract infection. Vitamin D serum concentrations are lowest during winter months. Plasma concentrations of 25-hydroxyvitamin D concentrations are lower in infants hospitalized with RSV infections compared with healthy controls,^{197,241} and a low 25-hydroxyvitamin D plasma concentration at birth correlates with a subsequent risk for RSV.¹⁹ Whether vitamin D supplementation can reduce the frequency and severity of RSV infection has not been determined.

Strain Variation

Variation in circulating strains of RSV has been suggested as partly accounting for the fluctuating clinical impact of RSV epidemics.^{13,221,245} The two major strain groups, A and B, differ mostly in the antigenic nature of the G and N proteins.^{192,226} Importantly, A and B strains usually circulate simultaneously during an outbreak. The proportion of strains from each group may vary by season and geography, as does predominance of the subgroups of A and B strains.^{13,192,226,245} In most areas, the usual dominant strains are in group A. In Rochester, New York, during a 20-year period, group A strains predominated in 11 of the years, group A and B strains were relatively equal in another 5 years, and in four seasons group B strains accounted for more than 75% of the year's isolates.¹³⁰ A study of strains from 14 cities across the United States demonstrated that the variability of strains occurs both seasonally and geographically.¹³ Several distinct but varying genotypes within the A and B strain groups predominate each year in a community, a finding suggesting that local preexisting immunity to previously circulating RSV strains may engender a selective advantage for strains with genotypes most diverse from those recently present in a community.^{192,226,295} Nevertheless, the relationship between the circulating strain group or subgroup and the size or clinical severity of an RSV outbreak has not been strong or consistent.^{200,226} Further understanding of these relationships and the molecular mechanisms, pathogenesis, and clinical importance of differing genotypes may be integral to the development of effective vaccines and the control of RSV. A novel genotype, named ON1, originated in Toronto and spread rapidly across the world. Nevertheless, despite the penetrance of this genetically new strain in most global areas, the severity of disease has not increased.^{84,261}

Acquisition and Ramifications of Infection

The availability of molecular-based detection techniques has allowed identification of a diverse group of viruses capable of causing lower respiratory tract disease.²⁶⁵ Although the reported proportion of hospitalizations attributable to each virus differs depending on the geographic area and the year, the most common pathogen in these studies is uniformly RSV, followed by human rhinovirus. During the first year of life, 50% to 70% or more of infants acquire RSV infection, despite the presence of maternal-specific neutralizing antibody in the sera of all newborns. The level of antibody in a term newborn is similar to the maternal level, which gradually declines during the first 6 months of life. In patients older than 7 months of age, detectable specific serum antibody usually is the result of natural infection. Essentially all children possess specific serum antibody by 3 years of age.^{104,225}

RSV accounts for 30% to 90% of bronchiolitis cases and up to 50% of pneumonia admissions during infancy. The major burden that RSV inflicts on the health care of children is illustrated by its ubiquity and the proportion of lower respiratory tract disease it causes in early childhood, especially among young infants. RSV accounts for 30% to 90% of bronchiolitis cases, up to 50% of pneumonia admissions during infancy, and 10% to 30% of cases of pediatric bronchitis.^{39,131} In contrast, only relatively small proportions, less than 10%, of croup cases have been associated with RSV infection. RSV is isolated rarely from patients (<1%) without respiratory disease.¹³¹ Fatal pediatric RSV cases are uncommon in industrialized countries. In the United States, the number of deaths associated with RSV infection each year among children younger than 5 years was estimated in 1985 to be 4500.²⁶⁷ During 1979 to 1997, this number was reported to have declined to an estimated 510 or less each year in children younger than 5 years.²⁵¹ An analysis of mortality rates between 2004 and 2011 among children hospitalized because of RSV reported fewer than 100 deaths per year.⁴⁴ The deaths often occurred mostly in patients with congenital heart disease and after several weeks of hospitalization, suggesting that RSV infection alone was not the cause of death.

In the United States, inpatient hospital charges for hospitalized children were estimated to exceed \$1.5 billion in 2009.¹³³ The economic and clinical costs related to RSV infections among young outpatient children have not been determined completely because costs from visits to emergency departments, clinics, and physicians' offices are difficult to quantify but are certainly quite substantial.¹³¹

Determination of the epidemiologic and clinical importance of coinfections in hospitalized children with bronchiolitis is an area of active research. Coinfection rates vary widely among studies and range from 6% to greater than 30%.^{15,62} Studies of coinfections oddly have not established whether disease severity is enhanced, reduced, or unaffected by coinfection.¹⁵

Reports that use nuclear amplification assays suggest that one or more viral respiratory pathogens (particularly rhinoviruses) can be isolated from the upper respiratory tract of as many as 30% of symptom-free young children.^{152,153} Whether viral genome detection in this setting represents prolonged shedding following a resolved infection, the incubation period for a pending infection, a persistent low-grade infection producing small amounts of virus, or infection by a serotype with limited ability to cause disease is not known.

The impact of RSV infections on communities around the world has been examined in numerous studies and varies depending on the geographic location, the population, and the methods of assessment. Nonetheless, several generalizations are evident: (1) RSV is highly contagious, resulting in ubiquitous infection by 2 to 3 years of age; (2) in this age group, RSV is the major cause of lower respiratory disease, predominantly bronchiolitis and pneumonia; (3) RSV infection of the lower respiratory tract in normal children almost always results from primary infection; (4) reinfections occur throughout life and tend to be milder and usually are upper respiratory tract infections; (5) the severity of illness from reinfections remains appreciable at any age in persons with comorbid conditions; and (6) medical visits by outpatients with RSV infection represent an appreciable portion of the burden to health care. Annual population-based hospitalization rates attributable to RSV from European countries are reported to be similar to those reported in the United States among children in different age groups.⁹³

Risk Factors for Severe Disease

Most infants hospitalized with RSV lower respiratory infection are full-term infants with no known risk factors. Chronologic age is the single most important determinant for severe bronchiolitis based on the observation that approximately two-thirds of pediatric RSV hospitalizations occur in the first 5 months of life. Hospitalization rates are highest between 30 and 90 days after birth.¹³¹ Infants with underlying chronic conditions are at high risk for requiring hospitalization for RSV illness, but numerous environmental and other host factors have been reported to augment the risk for a previously healthy infant's developing more severe RSV infection.^{104,244,255} These factors include becoming infected within the first few months of life, living in crowded and lower socioeconomic circumstances, geographic location, and gender. Although the rate of infection among girls and boys is equal, boys are hospitalized more frequently than are girls.

In the United States, an estimated 55,000 to 125,000 RSV-associated hospitalizations occur each year.^{156,198,294,292} The annual rate of hospitalizations caused by RSV compared with that from influenza or the parainfluenza viruses has been approximately three times greater for children aged 5 years and younger and six to eight times greater for children younger than 1 year.^{131,152,213} Adding to this burden of disease are emergency department and pediatric office visits, which occur at 5 to 10 times the rates for hospitalization.¹³¹

The rate of admissions attributable to RSV is markedly higher among infants within the first year of life than among children aged 1 to 4 years. In infants, the estimated rates have varied from 5 to 41 per 1000 each year, depending on the area and the methods used.^{36,176,189}

Population-based studies have reported annual hospitalization rates attributable to RSV in the United States of 3 to 3.5 per 1000 children younger than 5 years.^{36,131,160} These rates were approximately six times greater than those associated with the influenza viruses and three times greater than those associated with the parainfluenza viruses. The rates of hospitalization for RSV among infants were even greater, 12.9 per 1000 children younger than 1 year, compared with 1.7 for influenza and 3.2 for the parainfluenza viruses. The youngest infants, those younger than 6 months, had the greatest risk for requiring admission for their RSV infection, with a yearly rate of 17 per 1000 children.¹³¹

In other developed countries, population-based studies demonstrated similarly high rates of hospitalizations related to RSV among infants

and young children.^{93,189,213} Annual population-based hospitalization rates attributable to RSV from European countries were reported per 1000 children to be 2.5 for those younger than 4 years of age, 11 for children younger than 3 years of age, and 4 to 7 for those younger than 2 years of age. Among children within the first 12 months of life, 19 to 22 per 1000 children were admitted each year with RSV infection.⁹³

Children with certain comorbidities, including prematurity, chronic lung disease of prematurity, and congenital heart disease, may experience more severe RSV disease relative to children without such comorbidities.¹⁰ Studies indicate a marked increase in risk for severe RSV disease among preterm infants born before 29 weeks' gestation and those born between 29 and 35 weeks' gestation, relative to infants born at or after 36 weeks' gestation.³⁶ Current controversy exists as to whether premature infants born relatively later in gestation (32 to 35 weeks) are at higher risk for severe RSV disease.^{8,49}

Population-based data are not available on the incidence or severity of RSV disease among children who undergo solid organ transplantation or hematopoietic stem cell transplantation (HSCT), receive chemotherapy, or are immunocompromised because of other conditions. Progression of RSV infection from upper to lower respiratory tract disease depends on the virulence of the RSV strain as well as specific abnormalities in the immunocompromised host's immune response due to the underlying disease or to chemotherapy.^{81,140,166,238}

The magnitude of ambulatory visits among children resulting from RSV infection has not been well quantified and generally has received less attention. Surveillance conducted in Nashville, Tennessee, and Rochester, New York for acute respiratory illness occurring among children aged up to 59 months showed that RSV was the agent most frequently identified among ambulatory children evaluated for respiratory illness.¹³¹ RSV accounted for 18% of emergency department visits and 15% of pediatric practice visits from November to May. The estimated average rate of RSV-associated outpatient visits was 80 per 1000 children younger than 5 years and was estimated to be three times the rate of emergency department visits and 27 times the hospitalization rate for RSV. This appreciable impact of RSV outpatient visits on health care resources is further supported by a German study in which the annual incidence rate for RSV illness among outpatients was notably high at 77 per 1000 children younger than 3 years.⁹³

The economic and clinical costs related to RSV infections among young outpatient children have been poorly characterized. In the United States, the cost for emergency department visits was estimated in 1997 to 2000 at more than \$200 million per year for infants, and for all children younger than 5 years the cost for hospitalizations and other medical visits was \$652 million in 2000. The contributions to this economic burden from office practices have not been estimated but are likely significant.^{131,175}

Spread of Infection

RSV spreads effectively through exposed families, and introduction of the virus into the family appears to occur most commonly through a school-aged child. Serious disease in infancy is likely to follow a mild "cold" in an older sibling.¹²² In a prospective study of families with an infant and one or more older siblings, 44% of the families became infected with RSV during a 3-month epidemic. In almost all these families, older siblings (2–16 years of age) introduced the virus into the family, and the infants became secondarily infected (Table 182.2).

These clinical observations and volunteer studies indicate that RSV is predominantly spread by two modes: (1) large particle droplet aerosols (>10–100 μ m mass median diameter), which generally travel short distances (≤ 0.9 m) through sneezing, coughing, and even in some individuals by normal quiet breathing; and (2) self-inoculation of infectious secretions contaminating environmental surfaces.^{117,113} Small particle aerosols (≤ 10 μ m mass median diameter), which can produce distant spread, may also occur with RSV, but their clinical importance is controversial.

These modes of spread have been supported by volunteer and experimental studies. One study demonstrated that infection occurs in volunteers who touch surfaces contaminated by secretions and then their eyes or nasal mucosa.¹¹⁷ In contrast, no infections developed in volunteers exposed to infected infants at a distance of greater than 6

TABLE 182.2 Attack Rate of Respiratory Syncytial Virus in Families According to Age

Age (y)	CRUDE RATE ^a		RATE IN RSV-POSITIVE FAMILIES		SECONDARY RATE	
	No. ^b	%	No. ^b	%	No. ^b	%
<1	10/34	29.4	10/16	62.5	5/11	45.4
1–<2	2/7	28.6	2/5	40.0	0/3	0.0
2–<5	9/34	26.4	9/19	47.0	2/12	16.6
5–<17	9/48	18.7	9/24	38.0	4/19	21.0
17–45	9/55	16.8	9/21	43.0	6/18	33.3
Total	39/178	21.9	39/85	45.9	17/63	27.0

^aThe crude attack rate according to age is shown for all family members studied and for members of RSV-positive families. The secondary attack rate is also shown for members of RSV-positive families, excluding all primary and co-primary cases.

^bNumber of persons infected with RSV per total number of persons exposed.

From Hall CB, Geiman JM, Biggar R, et al. Respiratory syncytial virus infection within families. *N Engl J Med*. 1976;294:414-419.

feet, thus suggesting that small-particle aerosol spread of RSV was not a major mode of transmission. RSV infection therefore appears in most instances to require close contact with infected individuals or their secretions.

RSV in the nasal secretions of infants with acute infection remains infectious on countertops for longer than 6 hours and on cloth and tissue paper for approximately 30 minutes. These nasal secretions can remain infectious after transfer from objects or hands to the hands of another person, thus indicating that contact with clothing, furniture, or tissues contaminated by the secretions of infected children can result in spread.¹²⁰ Furthermore, the potential for RSV's transmission is augmented by the long duration of shedding and high viral loads commonly observed among young infants with RSV infection.^{73,119,300}

PATHOLOGY AND PATHOGENESIS

The incubation period of illness from RSV has been reported variably as being between 2 and 8 days, most frequently as 4 to 6 days. Experimental infection in adult volunteers produced an incubation period of 3 to 6 days, with an average of 5 days.^{121,171} With primary infection, the incubation period may be shorter.^{121,129} Inoculation is through the upper respiratory tract, followed by infection of the respiratory epithelium. Both the eye and the nose appear to be equally sensitive routes of inoculation.¹²¹ In contrast, inoculation by mouth results in infection much less frequently. Spread along the respiratory tract may occur by cell-to-cell transfer of the virus along intracytoplasmic bridges and may involve the conducting airways at all levels. However, aspiration of secretions into the lung during sleep cannot be excluded as a means by which virus may reach the lower lung.

The major pathologic findings shown in the lungs of infants dying from RSV bronchiolitis are (1) peribronchiolar mononuclear infiltration; (2) necrosis of the epithelium of the small airways; (3) plugging of the lumina with necrotic epithelial cells, leukocytes, and fibrin; and (4) hyperinflation and atelectasis (Fig. 182.3).^{6,154,292} The initial lesions in bronchiolitis occur in the small airways (75–300 μ m).²⁷⁸ Macrophage and neutrophil peribronchiolar infiltration develops, along with edema of the walls, the submucosa, and adventitial tissue. Lymphocytes, especially CD8 T cells, are notably absent in fatal RSV infections of infants²⁹² but are present in cases with milder outcomes.¹⁵⁴ Subsequently, the epithelium of the bronchioles undergoes striking necrosis, sometimes with proliferation of the epithelium into the lumen. Sloughing of necrotic material into the lumina of the small airways impedes the flow of air, which is aggravated by the presence of inflammatory debris.^{278,292} Amorphous material plugging the lumen is negative in stains for mucus (periodic acid–Schiff and Alcian blue), therefore more likely representing fibrin.²⁹²

Peripheral to the sites of partial occlusion, air trapping occurs, similar to a ball-and-valve mechanism. During the negative intrapleural pressure of inspiration, air can flow past the site of partial obstruction, but with the positive pressure of expiration, the lumen narrows, resulting in more complete obstruction and the hyperinflation characteristic of bronchiolitis. The trapped air may be absorbed and result in multiple areas of focal atelectasis. Functionally, these pathologic changes translate into an increased lung volume (unless atelectasis is extensive) and higher expiratory resistance in the infant. Pneumonia may be present concurrently and is marked by infiltration of mononuclear cells into the alveolar interstitium. The lung parenchyma appears edematous, with areas of necrosis leading to alveolar filling, consolidation, and collapse.

Initial recovery from acute bronchiolitis may be evident in 3 to 4 days, with regeneration of the bronchiolar epithelium, but ciliated cells rarely are present before 2 weeks.²⁷⁹ Complete histologic and functional recovery may require another 4 to 8 weeks.¹²³

IMMUNE RESPONSE: IMMUNITY AND DISEASE PATHOGENESIS

Despite the recent rapid rise in our knowledge of the immune response to RSV infection, it remains unclear whether disease results primarily

from the direct cytotoxic effect of viral replication or from the evoked immune response. Evidence for the direct viral replication being the prime cause has been long suggested by the observation of a correlation between increased RSV concentration in nasal secretions and disease severity seen in some studies,^{73,119,188} but not in others.^{187,300} Experimental studies in humans suggest that upper respiratory symptoms begin near the onset of viral shedding in nasal secretions, peak at the time of peak viral shedding, and begin to subside as viral load declines.⁷⁸ Nevertheless, because upper respiratory symptoms precede clinical signs of bronchiolitis and pneumonia by several days, it is unclear whether the degree of viral shedding will correlate with the time of development of severe forms of RSV illness in infants. More recent evidence showed that T-lymphocyte–derived cytokine concentrations in respiratory secretions of infants with RSV infection were lower than those in children with influenza infection.²⁹² In addition, lung tissue from infants with fatal RSV infection demonstrated abundant RSV antigen, but few CD4⁺ and CD8⁺ lymphocytes and few natural killer (NK) cells, leading to the conclusion that cytotoxic lymphocyte responses do not have an important role in the pathogenesis of RSV lower respiratory tract disease. Instead, severe RSV lower tract disease is characterized by abundant viral replication and an inadequate adaptive immune response.^{290,292} These findings suggest that during acute illness the pathogenesis of RSV disease is related more to the infant's inability to develop an adaptive cytotoxic T-cell response to curb viral replication than to an aberrant immune response that enhances the disease process.

Evidence supporting an immunopathic contribution comes from observations of enhanced disease among recipients of a formalin-inactivated RSV vaccine in the 1960s.¹⁶⁴ Current research also suggests that the innate and adaptive immune responses may participate in producing disease as well as limiting primary infection and immunizing against subsequent infection (Fig. 182.4). It is likely that both the direct effect of the virus and immune factors of the host are involved in causing disease following infection with RSV.²⁹⁰

Innate Immunity

RSV targets type I alveolar cells, airway epithelial cells, and alveolar macrophages, resulting in impairment of ciliary action and sloughing of infected epithelial cells.^{275,278} Dendritic cells scavenge the lung for foreign antigen and are important in generating a viral-specific immune response against RSV. After ingesting viral antigen, dendritic cells migrate to lymph nodes where antigen is presented to cognate, naïve T cells.¹⁰⁰ Cytokines released from dendritic cells polarize the cytokine responses toward a helper T-cell subtype 1 (Th1) or Th2 profile. Although it has been attractive to attribute wheezing in association with RSV infection

FIG. 182.3 Histologic examination of an infant dying of respiratory syncytial virus bronchiolitis. The arrow denotes a bronchiole filled with inflammatory exudate and comparatively normal alveoli.

FIG. 182.4 Schematic of the early innate and adaptive immune responses to respiratory syncytial virus (RSV). RSV's envelope glycoprotein G attaches to the respiratory tract epithelial cells (ECs) via glucosamine glycans expressed on the cell surface, and F interacts with antigen-presenting cells (macrophages, dendritic cells) via toll-like receptor 4 (TLR4) protein. This triggers the production and release of antiviral interferons (IFN- α , IFN- β , IFN- γ) and cascade of proinflammatory cytokines and chemokines. Two early nonstructural RSV gene products (NS1, NS2) antagonize IFN production. The chemokines recruit polymorphonuclear neutrophils (PMN), natural killer (NK) cells, and CD4⁺ and CD8⁺ T cells. A Th1-type cellular response becomes dominant under the influence of IFN- γ and interleukin (IL)-12, whereas under the influence of IL-4 and IL-13 the cellular response is skewed toward Th2 with the production of immunoglobulin E (IgE) and eosinophils (EOS).

to the induction of a Th2 response, there is virtually no evidence to support this in humans.⁹⁸

The infant's early innate immune response to the infection of these cells is characterized by the synthesis of chemokines and proinflammatory cytokines and the recruitment of inflammatory cells to the infected pulmonary tissues.^{154,155,246,269} Among these are neutrophils, eosinophils, and interferon- γ (IFN- γ)-secreting NK cells. There is a suggestion that strong innate cytokine responses are necessary to limit the severity of RSV infection.²³

Toll-like receptors (TLRs) have an important role in mediating and modulating the inflammatory cytokine and chemokine production during RSV infection. RSV's interaction with specific TLRs (TLR3, TLR4, TLR7, TLR8, TLR9) on mononuclear cells and alveolar macrophages results in production of antiviral and immunomodulatory mediators, including type I and III interferons; IFN- α , IFN- β , and IFN- γ ; chemokines CXCL8 (interleukin-8 [IL-8]) and CCL5 (RANTES), and cytokines IL-6 and tumor necrosis factor- α (TNF- α) (see Fig. 182.4).^{22,29,110,111,135,157,169,195,218,242} The outcome of RSV infection may vary according to the interaction of RSV with individual TLRs. This is illustrated in rodent models by TLR4-deficient mice having impaired viral clearance, whereas TLR3-deficient mice develop Th2-polarized responses but continue to eliminate virus with normal kinetics.^{135,242} Some evidence currently supports the role of TLR4 signaling in modulating human RSV disease.⁴⁶

Passively Acquired Antibody

During the neonatal period, protection against RSV infection is mediated in part by transplacentally acquired IgG. Glezen and coworkers showed that the age at the time of hospitalization for infants with primary RSV infection was directly correlated with the cord blood–neutralizing antibody titer.¹⁰⁴ Because maternally derived antibody has a half-life in the infant of approximately 21 days, the protective effect rapidly wanes. These observations, among others, led to the development and use of high-titered RSV intravenous immunoglobulin (RSV-IVIG) and, subsequently, of the monoclonal antibody palivizumab for RSV prophylaxis in high-risk infants.^{109,149}

B-Cell Responses

After acquiring RSV infection, infants develop antibodies to several RSV-specified proteins, the most important of which are directed against the F and G proteins, which have viral-neutralizing activity.³⁰³ Serum-neutralizing and F and G protein-specific antibodies develop in most infants after RSV infection, regardless of the severity of their illness.²⁹³ However, neutralizing and F antibody responses are diminished in those younger than 6 months, and high levels of preexisting maternal antibody inhibit antibody responses to the G protein. The antibody response to the F protein is broadly cross-reactive with both A and B strains because neutralizing epitopes are conserved between the two strain groups. This is in marked contrast to the group- and genotype-specific response to the highly variable G protein. Overall, the serum IgG response to RSV is relatively weak in infants. The strength of antibody responses increases with secondary infections.²⁹³ Titers may become undetectable within a year after infection, thus requiring several additional infections before levels approximate those found in adults.²⁷⁹ Levels of serum antibody are directly correlated with the degree of protection against natural reinfection in infants and adults,²⁸³ a finding confirmed in experimental challenge studies in adults.^{129,178} However, solid protection from reinfection is of brief duration at best because a substantial proportion of adults can be reinfected within several months of a naturally occurring infection.¹²⁹

During primary RSV infection of mice and humans, RSV-specific immunoglobulin A (IgA) antibody is detectable in nasal secretions and coincides with the cessation of viral replication, as judged by culture.^{129,257} Using a human adult challenge model, high levels of RSV-specific IgA antibody have been correlated with protection against symptoms following challenge.^{17,129} In addition to IgA antibody, RSV-specific IgE antibody has also been detected in nasal secretions during RSV infection, which correlated with an increased risk for the development of wheezing both during acute disease and later in childhood.²⁹⁴ Elevated levels of cysteinyl leukotrienes also have been detected in nasal secretions in

infants with RSV infection, although quantities of leukotrienes detected are not clearly related to the severity of illness.²⁷⁷ Mucosal antibody responses to nonreplicating RSV antigens are not strong but may be enhanced by the concurrent administration of ligands (TLR9/NOD2) before application.²⁴⁸

Efforts to develop a monoclonal antibody to be used for prophylaxis initially focused on the F protein because of its highly conserved amino acid sequence. By contrast, most portions of the RSV G protein are heavily glycosylated and highly variable, except for a short central motif that appears to be invariant. The G protein appears to induce neutralizing antibodies and protective immunity, but the G protein also has been implicated in disease pathogenesis, particularly modulation of the host immune response.^{156,219} The conserved region of the G protein demonstrates molecular mimicry with the chemokine fractalkine, which induces leukocyte transit to the site of inflammation. Both membrane-bound and secreted forms of G protein can bind to the fractalkine receptor CX3CR1, thereby blocking the interaction of fractalkine with its receptor and potentially interfering with the recruitment of NK cells and CD4⁺ and CD8⁺ T cells to the site of inflammation.^{42,272} Antibodies that block this motif of the G protein have been shown to reduce both viral replication and disease severity in animals.¹³⁴ However, there is tremendous duplication of chemokine functions in humans, and whether antibody to this G protein motif, or to the G protein itself, will modify disease in humans has not been established.

T-Cell Responses

Our understanding of cell-mediated immunity to RSV has been derived principally from studies in rodent models and from more limited information in humans. A hypothesis that has emerged from these studies is that the severity of disease is best controlled by the generation of Th1-dominant responses by IFN- γ -secreting CD4⁺ and CD8⁺ cytotoxic T lymphocytes, in concert with the combined effects of innate immune cytokines, serum neutralizing antibody, and mucosal antibody.^{17,98,142,252,256} Conversely, a Th2-polarized response, which induces IL-4- and IL-13-secreting CD4⁺ cells, eosinophils, and IgE antibody, theoretically would be associated with airway hyperreactivity and more severe disease.^{61,193}

RSV infection has been shown to have a wide spectrum of effects on T-cell immune responses.²⁰⁵ RSV, when added to in vitro cultures, has inhibitory effects on lymphocyte proliferative responses. In addition, dendritic cells, including those recovered from RSV-infected infants, have diminished capacity to activate CD4⁺ T cells in vitro.^{58,70,100,184} Nonetheless, RSV infection can induce a full range of T-cell responses in vivo, including Th1 CD4⁺ and CD8⁺ cytotoxic T lymphocytes as well as Th2 CD4⁺ cells. These responses are, however, generally quite weak in human infants with RSV infection.¹⁹⁴ Human and murine CD8⁺ cytotoxic T lymphocytes recognize F, M2, M, and NS2 epitopes in the context of class I antigens.^{38,53,57,136} Both CD4⁺ and CD8⁺ T cells can clear virus from the lungs of infected animals. However, disease in mice is mediated by excessive T-cell responses; removal of CD4 or CD8 T cells permits greater virus replication, but illness is less severe.¹⁰⁶ The relevance of these studies to human disease, where illness seems related to inadequate cytotoxic lymphocyte responses,²⁹² is unclear. Also, although a predominance of Th2 lymphocytes has been hypothesized as a factor in severe forms of RSV infection, most studies have failed to detect the presence of Th2 cytokines in human infants with RSV disease.^{3,98,252,271,292} In one report, RSV-specific lymphoproliferative responses were relatively short-lived after primary infection and were not boosted by reinfection.³³ RSV is a poor inducer of protective central memory T-cell responses, perhaps accounting in part for the failure of long-term immunity after infection.⁵³

In summary, humoral and mucosal antibodies provide some protection from infection, although it is variable and transient. The innate and adaptive T-cell responses elicited by RSV infection may have a role in determining the disease pathogenesis and in viral clearance. Host and environmental factors favoring the induction of Th1 responses, either during natural infection or possibly following vaccination, may minimize pathologic changes, disease severity, and perhaps subsequent airway hyperreactivity. Despite considerable research, there is minimal evidence suggesting that induction of Th2 cytokine responses contributes to the severity of RSV infection or is linked to the development of wheezing episodes following infantile bronchiolitis.

FIG. 182.5 Clinical diagnoses of children with respiratory syncytial virus (RSV) infection according to age. The proportion of children presenting with each respiratory syndrome who were younger than 6 months and had primary RSV infection is shown in comparison with those children aged 2 to 5 years who had a repeated RSV infection. Data were obtained from 415 outpatient infants and children evaluated in Rochester, NY. (Courtesy C.B. Hall, unpublished data.)

CLINICAL MANIFESTATIONS

*We view their chests ballooning, with the fears
that they're "pink puffers" of more tender years.*

—C.B.H.

Primary Infection

An infant's first encounter with RSV almost always is apparent, but the symptoms may range from those of a mild cold to severe bronchiolitis or pneumonia. Various definitions of bronchiolitis have been proposed, but generally the term *bronchiolitis* is limited to infants less than 12 to 18 months of age with wheezing precipitated by a viral infection. An infant with bronchiolitis typically presents during the winter months after 2 to 4 days of low-grade fever, nasal congestion, and rhinorrhea with symptoms of lower respiratory tract illness, including cough, tachypnea, and increased respiratory effort as manifested by grunting, nasal flaring, and intercostal, subcostal, or supraclavicular retractions.¹²⁴ Rarely is a child's first encounter with RSV entirely asymptomatic. Among infants examined over the course of a 10-year period with known primary RSV infection who initially were younger than 6 months, 45% had the clinical manifestations of bronchiolitis or pneumonia, compared with 5% of children 2 to 5 years of age who had experienced two or more outbreaks of RSV infection (Fig. 182.5).²²⁵ Higher rates of lower respiratory tract disease have been documented to occur in children with underlying cardiopulmonary disease, those in closed populations such as group child care centers, and those from certain geographic areas or with particular ethnic backgrounds.^{139,186}

In the longitudinal Houston family studies,¹⁰⁵ 69% of children in their first year of life acquired RSV infection, and one-third of these infections were lower respiratory tract illnesses. By the time they were 24 months of age, essentially all children had been infected at least once and about half had experienced two infections, such that the rate of infections during the second year of life was 83%. The proportion of RSV infections involving the lower respiratory tract remained appreciable during the second, third, and fourth years of life, but the severity decreased. In general, lower respiratory tract illnesses associated with RSV after the second year of life most frequently are tracheobronchitis and reactive airway disease.¹⁰⁵

Pneumonia and bronchiolitis, the most common forms of RSV lower respiratory tract disease in infants, generally coexist and are nearly impossible to differentiate clinically or radiographically. Children with hyperinflation and wheezing, the hallmarks of bronchiolitis, may have densities on a chest film that may appear similar to infiltrates from pneumonia (Fig. 182.6). However, in bronchiolitis, these shadows most likely result from atelectasis rather than from the interstitial inflammation and alveolar filling of pneumonia.

FIG. 182.6 Bronchiolitis from respiratory syncytial virus (RSV) infection. This chest radiograph of a 3-month-old infant with bronchiolitis from RSV infection shows hyperaeration of the lung and area of atelectasis in the right middle lobe.

Upper respiratory tract symptoms usually precede lower respiratory tract involvement by several days. Low-grade fever is a common manifestation during this initial phase of the illness, but it may have disappeared by the time of hospitalization (Fig. 182.7). Among 565 children hospitalized with RSV infection, fewer than half had a temperature higher than 38°C (100.4°F) at the time of admission.¹²⁸ Among children undergoing their second, third, or fourth infections, 20% to 40% of children may be febrile.¹³⁹

Increased coughing commonly heralds involvement of the lower respiratory tract, which subsequently may be indicated by an increased respiratory rate, dyspnea, and retractions of the chest wall (see Fig. 182.7). Auscultatory findings of crackles and wheezing may be present on initial examination but absent on reexamination shortly thereafter. Variability of the child's clinical findings within minutes to hours is characteristic of RSV lower respiratory tract disease. Ill children who elicit concern because they are lethargic and short of breath may have minimal audible wheezing and crackles because of limited air entry with inspiration. There is not a consistent correlation between the findings on auscultation or on the chest radiograph with severity of disease or with length of hospital stay. Respiratory rate and the degree of chest wall retraction are better predictors.

Radiographic Findings

The radiographic findings in infants hospitalized with RSV lower respiratory tract disease may be variable, but with bronchiolitis, hyperinflation with hyperlucency of the lung, flattened diaphragms, and peribronchiolar thickening usually are evident. Patchy areas of atelectasis also may be present, most often in the right middle and upper lobes. Areas of atelectasis may be large and are too often interpreted as representing bacterial pneumonia. Less frequently observed are interstitial infiltrates of pneumonitis, which tend to be present diffusely (see Fig. 182.6).

Current guidelines recommend that bronchiolitis should be diagnosed on the history and physical examination and that chest radiographs should not be obtained routinely. Infants with bronchiolitis will have abnormalities on a chest radiograph, but data do not indicate that the chest radiograph findings correlate well with disease severity. Routine radiography has been shown to increase the risk for receipt of antibiotics without any impact on outcome. Initial radiography should be reserved for cases in which respiratory effort is severe enough to warrant intensive care unit (ICU) admission or where signs of airway complication (such as pneumothorax) are present.¹⁹

FIG. 182.7 Clinical manifestations in children with respiratory syncytial virus (RSV) infection who were evaluated in Rochester, NY. Shown are the proportions of 1132 hospitalized children compared with the proportions of 489 outpatient children with each clinical sign.

With tracheobronchitis and upper respiratory tract infections, the accompanying signs and symptoms tend to be more severe in RSV infection than in infections with other common respiratory agents. Coughing is often prolonged. Otitis media frequently is associated with both initial RSV and recurrent RSV infection.^{137,230} Among children with RSV infection, the virus has been detected in 30% to 74% of middle ear aspirates. Among children presenting with otitis media, RSV is one of the most frequently identified viral pathogens and has been associated with prolonged symptoms and apparent failure of therapy. RSV may be detected as the sole pathogen or simultaneously with a bacterial agent, thus suggesting that RSV may play both a primary and a secondary role in the pathogenesis of otitis media.²⁹⁷

RSV infection has been associated occasionally with a variety of neurologic, cardiac, and other conditions.^{18,210,260} However, in most of these reports, the causal role of RSV is arguable; alternatively, a simultaneous RSV infection may be occurring that is unrelated to the more unique clinical event.

Infection in Neonates

Symptoms of RSV infection are largely dependent on the age of the host at the time of infection. In Washington, DC, the incidence of RSV infection during the first month of life was noted to be only one-third of that during the second month of life.²²⁵ The protected environment of newborns with diminished exposure to others, as well as the high levels of maternal antibody or other early immune factors, may explain the lower incidence of illness in the neonatal period. RSV infection in neonates may be variable and atypical. Apnea and hemodynamic instability may occur in the presence of only with minimal respiratory signs, resulting in an incorrect or delayed diagnosis.¹²⁵ Apnea usually develops at the beginning of the RSV infection before wheezing occurs, often as the first manifestation of illness, and is short-lived and non-obstructive.¹² Most infants do not have apnea subsequently, even with later respiratory tract infections.

In full-term infants, RSV infection in the neonatal period may manifest primarily as a mild, afebrile upper respiratory tract illness, often associated with atypical findings such as feeding difficulties, poor weight gain, periodic breathing, or apnea.¹² However, among premature infants, the morbidity may be more pronounced. During a community outbreak of RSV infection in Rochester, New York, 25% of infants kept in a neonatal ICU for more than 6 days acquired RSV infection. Infants older than 3 weeks of age tended to have lower respiratory tract disease characteristic of RSV infection and apnea, whereas infants in the first 3 weeks of life were more likely to have nonspecific findings without clinical evidence of lower respiratory tract disease. Fewer than half had upper respiratory tract signs; nonetheless, four (17%) of the infants died.¹²⁵

Acute Complications

Apnea, a major complication of acute RSV infection in young infants, occurs in 1% to 20% of infants hospitalized with RSV infection.^{12,124,234}

Apnea is most likely to occur among infants born prematurely, in those with a young postnatal age, especially infants who have not yet reached a postconceptional age of 44 weeks, and in infants with a history of apnea of prematurity. The apnea usually develops at the beginning of the RSV infection, often as the first manifestation of illness, and is short-lived and nonobstructive.¹² Most infants do not have apnea subsequently, even with later respiratory tract infections.

Simultaneous or secondary bacterial infection appears to be a relatively frequent complication of RSV infection in some countries in the developing world.^{208,270} In the United States and other developed countries, it is an unusual complication, and most clinical and pathologic studies indicate that RSV infection rarely predisposes to acquisition of a bacterial infection.^{128,232}

In a 9-year prospective study of 565 children hospitalized with RSV lower respiratory tract disease, the rate of subsequent bacterial infection was 1.2% in the total group of children infected with RSV and 0.6% in the 352 children who received no antibiotics.¹²⁸ If a bacterial infection is present simultaneously, it most frequently involves the urinary tract. The diagnosis is made by a positive urine culture (using the criterion of 50,000 colonies/mL) in about 3% of infants.^{180,198,232,236} Concurrent urinary tract infections, however, may be coincidental to RSV infection or may represent asymptomatic bacteriuria. Serious concurrent bacterial infections are unusual enough that evaluations for sepsis and meningitis, and the empiric use of antibiotics, are not recommended routinely.⁹ Controlled studies with randomized antibiotic treatment of lower respiratory tract disease caused mostly by RSV have shown no difference in the severity or duration of illness or in the child's outcome.⁹

More frequently, coinfection with other respiratory viruses occurs.^{146,179,190,191} Using real-time polymerase chain reaction (PCR) assays, infection with two or more viruses has been reported to occur in more than 15% of hospitalized children with acute respiratory tract infection.^{34,146} Studies examining whether coexistent viral infections in normal children augment the severity of infection show mixed results.^{19,146,190,191} Among the commonly found agents that are simultaneously detected in young children with RSV infection are adenoviruses, rhinoviruses, hMPV, bocavirus, enteroviruses, influenza viruses, and parainfluenza viruses.¹⁹¹ Respiratory disease from bacterial coinfection is uncommon, but bacterial pathogens have been detected simultaneously in the respiratory secretions of children intubated for RSV infection, including *Staphylococcus aureus*, *Bordetella pertussis*, *Bordetella parapertussis*, *S. pneumoniae*, *Moraxella catarrhalis*, and *H. influenzae*.^{214,258,264,282} These bacterial isolates likely represent colonization among infants with

RSV infection, often being found with approximately equal frequency in intubated, uninfected, control infants.

PROGNOSIS

*Thus, if infected at this tender stage
will they become “blue bloaters” as they age?*

—C.B.H.

Prediction at Time of Initial Evaluation

Determining whether an infant with RSV infection who initially presents as an outpatient is likely to require subsequent hospitalization has been problematic. Numerous clinical findings have been evaluated, but most have relatively poor predictive value for individual patients.⁹ Among the more consistent and helpful findings at the time of evaluation are oxygen saturation and global assessment of the degree of illness. Fever does not correlate with the severity of disease.⁴⁰ Tachypnea (≥ 70 breaths/min) has been mildly correlated with the presence of lower respiratory tract infection in infants and progression to the need for intensive care.^{9,40} Repetitive assessments are helpful because rapid fluctuations in clinical manifestations are characteristic of RSV lower respiratory tract disease.

Clinical scoring systems commonly are used, but their use is limited by variable design, rendering comparison and standardization difficult. The Respiratory Distress Assessment Instrument has been standardized, but it is not validated in predicting the severity or outcome of children with bronchiolitis.⁹ Another report described a scoring system to predict which healthy, term newborns in the Netherlands are at increased risk for RSV lower respiratory tract infection during the first year of life.¹⁴³ Independent predictors for RSV lower respiratory tract disease were group child care attendance and/or having siblings, birth weight less than 4000 g, birth outside of the months of April to September, and a low level of parental education.

Pulse oximetry is a convenient method to assess the percentage of hemoglobin bound by oxygen in vivo. However, only a moderate correlation exists between respiratory distress and oxygen saturations among infants with viral lower respiratory tract infections, and the use of oximetry has been demonstrated occasionally to prolong hospitalizations unnecessarily.²⁴⁷ The difficulty seems to center around the use of an oxygen saturation of 95% as a criterion for admission and discharge. Using a lower value, perhaps 92%, may improve the precision of oximetry in determining the need for admission or continued hospitalization.

Infants hospitalized on inpatient floors for RSV infection rarely require subsequent transfer to ICUs. The risk in one study was 1.2%, with young age and high respiratory rates providing the best predictive value.⁴⁰

Infants hospitalized with RSV bronchiolitis or pneumonia usually show clinical improvement within 24 to 48 hours, and most previously normal infants are discharged within 1 to 7 days, most commonly after 2 to 3 days in the United States.^{9,233} However, children with underlying conditions that increase their risk for developing more complicated illness may require a longer hospitalization. Among infants in the first year of life who present to the emergency department with bronchiolitis, the median duration of symptoms until complete recovery was 15 days, and this did not vary in regard to viral etiology.²²⁹

Patients at Risk for Complicated RSV Infection

The primary risk factors for hospitalization and increased severity of RSV infection are premature birth, underlying congenital heart disease, and particularly bronchopulmonary dysplasia. Infants with these conditions have rates of hospitalization that are many times that of the population without these factors.^{7,37,149,285} Secondary factors reported to be associated with an increased risk for severe RSV disease include a greater number of older siblings, impaired neuromuscular function or certain congenital malformations, low socioeconomic status, crowded living conditions, birth during the first half of the RSV season, multiple births, exposure to indoor air pollution including secondhand smoke, malnutrition, living at an altitude greater than 2500 meters, Down syndrome, nonwhite race, and low antibody concentration in cord blood. Other chronic diseases, chromosomal abnormalities, and congenital

malformations have been associated with an increased risk for RSV hospitalization.^{43,61,72,92,168,233,239} However, these secondary risk factors either have been reported inconsistently or have been associated with only a slightly increased risk for hospitalization.¹⁷⁴

Infants with hemodynamically compromising congenital heart disease, particularly conditions associated with pulmonary hypertension or cyanosis, have been shown to have a markedly elevated risk for fatal outcomes.⁴⁴ The mortality rate of children with certain functionally important cardiac conditions has declined from greater than 30% to approximately 3%.⁴⁴

Deficits in innate and adaptive immunity have long been assumed to predispose a child to the development of more severe forms of RSV infection, but the nature of these defects remains mostly undefined. More recent studies show some correlation of genetic polymorphisms with primary RSV disease and severity. Variations within a number of genetic loci potentially associated with controlling immune function, such as the expression of IL-4 and other T-lymphocyte cytokines and chemokines associated with the production of IgE antibody and hyperactive airways, have been shown to be overrepresented in children with RSV lower respiratory tract disease and with disease that is more severe^{61,141,147,172,217,262} (see [Immune Response: Immunity and Disease Pathogenesis](#)).

Immunocompromised Patients

RSV infection can occasionally become life-threatening in subjects with severe immune deficiencies, either from acute infection or by causing the long-term development of bronchiolitis obliterans.^{62,83} The risk for RSV infection becomes more significant with increasing numbers of highly immunosuppressed patients, such as recipients of bone marrow and solid organ transplants.²¹² Progression of RSV infection from upper to lower respiratory tract disease depends on the degree of specific vulnerabilities in the immunocompromised host's immune response because of the underlying disease or to chemotherapy.^{81,140,166,238} Lymphopenia has been recognized as a risk factor for disease progression in several studies of immunocompromised patients. One study in adults noted that progression of RSV to lower tract disease did not occur in patients with a lymphocyte count greater than 1000 cells/mm³ at time of onset of upper respiratory tract infection. An absolute lymphocyte count of 100 cells/mm³ or less at the time of RSV upper tract infection was associated with nearly uniform progression to lower tract disease. In contrast to lymphopenia, analysis of antibody concentration in these adult HSCT patients indicated no correlation between preexisting anti-RSV antibody concentration and progression from upper to lower respiratory tract disease.¹⁶⁶

Reported risk factors for a poor outcome due to RSV infection in an immunosuppressed child include age less than 2 years, presence of lower respiratory tract symptoms at presentation (particularly in the absence of symptoms of upper respiratory infection), and varying degrees of lymphopenia.⁵⁵

RSV infection has been reported as occurring in approximately 50% of bone marrow transplant recipients and often is acquired nosocomially.² The morbidity and clinical manifestations associated with RSV in these patients are highly variable.^{2,32,31,51,63} Risk factors for development of more severe disease in transplant recipients include not only the degree of immunosuppression but also allogeneic transplantation, acquisition of the RSV infection within 2 months of undergoing transplantation but before engraftment, and the presence of graft-versus-host disease. The associated mortality rate among transplant recipients with lower respiratory tract disease has been reported as 70% to 100%, but mortality has been reported more recently as ranging from 0% to 50%, depending on the patient population.^{161,163,243} Findings on the chest radiograph include focal interstitial infiltrates, sometimes associated with lobar consolidation or with hyperinflation, or more severe involvement of generalized alveolar and interstitial infiltration, and marked hypoxemia. The major findings with high-resolution computed tomography (CT) are small centrilobular nodules, airspace consolidation, ground-glass opacities, and bronchial wall thickening. These abnormalities frequently are present in both the periphery and central areas of the lung, are bilateral, and are asymmetric in distribution.³¹

RSV infection in immune-compromised subjects may not be recognized or considered because it may occur when RSV is not circulating

in the community, and the clinical picture may mimic that of other opportunistic agents that commonly infect immunocompromised patients. Furthermore, establishing the diagnosis is problematic because the most frequently available assays—rapid antigen assays applied to swabs of upper respiratory tract secretions—often lack sensitivity in these patients. Greater accuracy is achieved using quantitative PCR assays in specimens obtained through bronchopulmonary lavage specimens.⁴⁷

Instituting therapy with ribavirin in RSV-infected patients while they still have only symptoms of upper respiratory tract infection has shown variable results in terms of survival.^{55,249} Outcomes may be improved with the combined use of ribavirin and palivizumab,⁵⁵ but larger, controlled studies are needed to establish the optimal form of treatment. Because many RSV infections on a hematology-oncology ward are nosocomial, strict enforcement of infection control policies is critical.²⁴⁶

Patients With Human Immunodeficiency Virus Infection

RSV infection may be more severe among HIV-infected children. In a cohort of South African children observed for 5 years, the incidence of hospitalization from RSV lower respiratory tract disease in children with HIV infection was three to five times greater than that in those not infected with HIV, and RSV deaths were increased 31-fold.²⁰³ Studies have not confirmed a similar risk in HIV-infected children in the United States or United Kingdom, perhaps related to better care for HIV-infected children in developed countries.^{52,65,167}

Pulmonary Sequelae

RSV infection in infancy is associated with an increased risk for wheezing in childhood and perhaps longer. Abnormalities of lung function have been noted in later childhood following infantile bronchiolitis as well, although the risk is also associated with respiratory viruses other than RSV.^{94,110,166,214,298,302} Variations on three basic theories have been proposed to explain the link between early RSV infection and subsequent asthma. One possibility, a causal relationship, is that changes induced by viral replication alter the pattern of normal lung development in such a way that the infant is predisposed to subsequent episodes of wheezing. A second possibility, a triggering relationship, is that certain infants have a preexisting aberration of either airway function or the immune response, and early viral infection serves as a triggering event to episodes of acute airway obstruction. For example, several polymorphisms in cytokine genes have been associated with RSV severity and asthma suggesting a shared predisposition.^{94,148,215,257,268} A third possibility is that a preexisting abnormality of airway function (possibly airway hyperreactivity) predisposes to wheezing with viral bronchiolitis in infancy and again with allergen exposures in later life. Intervention studies with a vaccine or other preventive and therapeutic measures will determine the presence of a link between RSV bronchiolitis and subsequent wheezing illnesses.

Repeated Infection

Recurrent infections with RSV occur across the age span from toddlers to elderly persons, whether healthy or infirm. Reinfection occurs most frequently among those in close contact with young or school-aged children, as in group child care facilities and primary schools, or among those in confined settings, including military recruits.^{105,127,112,139,220} Most of these infections are upper respiratory tract illnesses, which often are complicated by sinusitis and otitis media. Recurrent infections involving the lower respiratory tract usually are manifest as tracheobronchitis or as exacerbations of wheezing. Even among young, healthy adults without asthma or other chronic pulmonary conditions, acute RSV infection produces hyperreactivity of the airways that may persist for as long as 8 weeks.¹²³

Among children observed longitudinally, as many as three-fourths can be reinfectd each year. Among children in group child care, attack rates of 98%, 75%, and 65% have been reported for first, second, and third infections, respectively. Immunity resulting from a single infection appeared to have no ameliorating effect on illness associated with reinfection 1 year later. Not until the third infection was severity reduced appreciably.¹³⁹ Among preschool-aged children, 20% to 50% of the

repeated RSV infections involved the lower respiratory tract, but the illness tended to be milder than that following primary RSV infection.¹⁰³ Most children had lower respiratory tract illness only once, and those with repetitive lower respiratory tract infections had other features suggesting the presence of asthma.

Healthy adults frequently are exposed to RSV in their workplace and as parents or members of families with preschool-aged and elementary school-aged children. Despite these repetitive exposures, most subjects remained susceptible to RSV infection during the subsequent outbreaks and, if infected, developed symptoms.^{127,220,283} Very recent infection, however, may result in diminished symptoms. In one study, 15 previously well adults became naturally infected with an RSV A strain during a community outbreak and developed upper respiratory tract illnesses (Fig. 182.8). These individuals subsequently were inoculated intranasally with an RSV A strain at repetitive intervals over the course of 2 to 26 months. The number reinfectd and the proportion manifesting any symptoms continually declined during the 26 months. The quantity and duration of virus shedding also diminished concurrently.¹²⁹

Among 211 working adults observed over the course of multiple seasons, RSV reinfection was symptomatic in 84% and manifested as an upper respiratory tract illness in 74%.¹²⁷ The remaining fourth of the reinfections caused tracheobronchitis or wheezing. Some individuals became infected with RSV and, later, with both RSV and influenza virus simultaneously. Comparison of the two illness episodes revealed that symptoms associated with influenza and RSV were generally similar (Fig. 182.9), although influenza was accompanied more frequently by fever and absence from work, whereas RSV infection was associated significantly more often with sinusitis, otitis, and a longer duration of illness.

The clinical similarity of illness from RSV and from influenza among young adults and the difficulty of differentiating the two also were shown in university students and in military recruits.^{185,220} Findings associated with RSV and influenza infections were similar, except that wheezing was associated more frequently with RSV infection. The proportion of patients requiring inpatient confinement was the same for those with RSV infection as for those with influenza.

The importance of RSV infection as a cause of morbidity and mortality in older adults, both those previously healthy and those with underlying conditions, is being recognized increasingly.^{88,281,298} Between 2% and 9% of all lower respiratory tract hospitalizations in elderly persons have been estimated to be caused by RSV, with an estimated annual cost of more than \$1 billion.⁸⁸ Additional hospitalizations and costs may be incurred from the exacerbations of underlying chronic conditions associated with unrecognized RSV infections.

The impact of RSV infection in elderly individuals was illustrated in a prospective, multiyear study of 608 healthy community-dwelling elderly patients and 504 adults with high-risk conditions. An additional 1388 individuals who were hospitalized with acute cardiopulmonary conditions also were studied.⁸⁸ The mean age of the individuals studied ranged from 70 to 75 years. Using viral isolation, reverse transcriptase polymerase chain reaction (RT-PCR), and serology, RSV infection was identified at an annual rate in 3% to 7% of the healthy cohort, in 4% to 10% of the high-risk group, and in 8% to 13% of the hospitalized patients. In comparison, influenza A infection was detected annually in 2% to 4% of the healthy elderly cohort, in 1% to 5% of the high-risk group, and in 1% to 20% of hospitalized patients. The illnesses from RSV and influenza A could not be distinguished clinically. Among the hospitalized patients, intensive care was required by 15% of those with RSV and by 12% of those with influenza A infection; 8% of the RSV and 7% of the influenza A infections were fatal. Although RSV infection generated fewer office visits than did influenza among the healthy, older age group, those with high-risk conditions used health care services similarly if they were infected with RSV or influenza. The impact on health care services and costs by RSV is underscored by the proportion of hospitalizations caused by RSV for pneumonia (10.6%), chronic obstructive pulmonary disease (11.4%), congestive heart failure (5.4%), and asthma (7.2%). The role of RSV in elderly patients with these diagnoses frequently is unrecognized.

Further evidence of the burden of RSV disease is provided by a prospective, three-season study evaluating patients 50 years or older

FIG. 182.8 Reinfection with respiratory syncytial virus (RSV). Proportion of young adults with natural RSV A infection who became reinfected, shed virus, and were symptomatic when they were subsequently rechallenged intranasally with RSV A after intervals of 2, 4, 8, 12, 20, and 26 months from time of their natural infection. (From Hall CB, Walsh EE, Long CE, Schnabel KC. Immunity to and frequency of reinfection with respiratory syncytial virus. *J Infect Dis.* 1991;163:693-698.)

FIG. 182.9 Respiratory syncytial virus (RSV) infection and influenza. Comparison of clinical findings observed during RSV infection compared with influenza infection among 211 prospectively followed previously healthy adults who acquired both infections, RSV infection at one time and influenza infection at a separate time. (From Hall CB. Nosocomial respiratory syncytial virus infections: the "cold war" has not ended. *Clin Infect Dis.* 2000;31:590-596.)

admitted to the hospital with respiratory symptoms caused by infection attributable to RSV, hMPV, or influenza viruses.²⁹⁶ The length of hospitalization, rate of admission to the ICU, number of days spent in the ICU, need for mechanical ventilation, and death were no different among patients infected with any of the three viruses. The rates of hospitalization during the 3-year period were 15.0, 9.8, and 11.8 per 10,000 residents for infection caused by RSV, hMPV, and influenza, respectively. For adults 65 years or older, rates of hospitalization were statistically higher for those with RSV and hMPV infections than for those with influenza. RSV accounted for 6.1% of hospitalizations for acute respiratory illness in these elderly individuals over the 3 years. In a separate study among high-risk adults 65 years or older, hospitalization rates were estimated at 23.4 per 10,000 for infections with both RSV and influenza.²⁰⁴

DIAGNOSIS

A presumptive diagnosis of RSV lower respiratory tract disease often is made on the basis of the age of the child, the presence of symptoms of bronchiolitis, and presentation within the usual period of peak RSV seasonal activity (if not monitored locally, nationwide data are available through the Centers for Disease Control and Prevention).⁵⁰ A marked increase in the number of outpatient visits and admissions for bronchiolitis and respiratory illness in children younger than 2 years usually is a strong indication that RSV is active within the community (see Fig. 182.2).¹¹⁶

However, PCR techniques have shown that an increasing number of viruses other than RSV may produce clinically similar illnesses, although the intensity of epidemic activity with these other viruses is

still less than that caused by RSV.^{126,289,299} Routine viral testing of out-patient or hospitalized young children with bronchiolitis is not recommended in the Clinical Practice Guidelines from the American Academy of Pediatrics.⁹ However, viral testing may be useful for epidemiologic monitoring, for evaluating children with an atypical presentation, or for decisions regarding cohorting of particularly high-risk patients.¹²⁶

A specific diagnosis of RSV infection alternatively may be made by viral isolation using standard cell culture or shell vials, direct and indirect fluorescent assays, and enzyme immunoassays, when PCR technology is not available. Nevertheless all of these methods lack the sensitivity and specificity of PCR.²⁰⁶ Indirect and direct fluorescent assays and enzyme immunoassays applied to nasopharyngeal secretions from children, especially infants, have an average sensitivity and specificity of approximately 95% when these tests are performed by experienced personnel.¹¹⁴ However, the ranges of sensitivity and specificity depend on the laboratory's expertise. These tests are less sensitive than PCR in older children and adults, who have preexisting antibody in secretions that may interfere with detection of RSV. False-positive results may occur when non-PCR tests are used during seasons of the year in which RSV activity is low.

The specimens employed for diagnosis usually are upper respiratory tract secretions from a nasopharyngeal swab or, less frequently, nasal aspirate. A flocked nasal swab is satisfactory for detection of RSV by PCR, but nasal washing or tracheal aspiration is more sensitive than is a nasopharyngeal swab specimen if the other diagnostic techniques are be used.¹³⁸ Nasal wash specimens may be obtained with a suction apparatus or by the use of a tapered rubber bulb (Fig. 182.10).

In the past, tissue culture isolation of the virus was the standard technique used for establishing the diagnosis of RSV. However, culture techniques now are used less frequently because of the added expense, the greater number of days required until a syncytial cytopathic effect appears (an average of 3–5 days), the need for considerable technical expertise and time, and the need for reliably sensitive tissue culture.¹¹⁵

PCR techniques consistently have been shown to be the optimal means for detecting viral infections among populations of children and adults, and they detect 30% or more infections than do viral isolation techniques.^{87,185,288} Nested PCR assays add sensitivity, allow multiple viruses to be identified simultaneously, and help to differentiate RSV group A versus B strains. RT-PCR assays have the advantages of rapidity because of a diminished number of procedural steps and of a decreased chance of contamination, but they may be limited in the number of viruses that can be detected concurrently. Quantitative RT-PCR has the further advantage of determining the viral load, which correlates with viral quantitation by culture during the early phase of infection. In

FIG. 182.10 Simple method for obtaining nasal wash specimens from young children. A 1-oz tapered rubber bulb is used to inject and collect 5 to 10 mL of saline with one squeeze. (From Hall CB, Douglas RG Jr. Clinically useful method for the isolation of respiratory syncytial virus. *J Infect Dis*. 1975;131:1-5.)

contrast, PCR signals persist well beyond the time when virus is no longer detectable by culture.^{76,265,274} In addition, higher viral loads may predict a more severe clinical course,^{73,144} although not all studies agree.¹⁸⁷ A considerable proportion of symptom-free children have specimens positive by PCR to various respiratory viruses, although this occurs less commonly with RSV than with other viruses, particularly rhinoviruses.²⁶⁶ This may be related to the sensitivity of PCR techniques to detect low levels of shedding during the convalescent phase of a previously symptomatic infection, or indicate a concurrent asymptomatic viral infection. It is also possible that detection by PCR may indicate persistence of RSV infection somewhere in the epithelial or inflammatory cells of the lower airways.

Serologic diagnosis usually is reserved for research purposes because it generally is not helpful in the acute diagnosis and management of patients. A detectable serologic response is inconsistently observed in infants, even among those with severe disease.^{94,293} Serologic assays commonly include neutralizing antibody assays against whole virus, and enzyme immunoassays using purified F and G proteins of RSV to detect IgM and IgG responses. A number of other assays are used in research. Serologic diagnosis appears to be more sensitive among elderly than younger subjects.²⁸⁰ Using the presence of a single high titer to identify infection has led to variable results and is not employed currently.

TREATMENT

For most children with RSV lower respiratory tract disease, supportive care is sufficient. Monitoring hydration status and oxygenation and, when necessary, clearing the nasal passages by gentle bulb suctioning are important. Respiratory rates of more than 60 to 70 breaths per minute are likely to compromise the infant's ability to take fluids, creating the need for intravenous hydration. The administration of supplemental oxygen to infants with this degree of tachypnea may be necessary to make the infant more comfortable and to prevent tiring.³¹²

The criteria for determining the need for administration of supplemental oxygen to previously healthy infants are not well defined. A correlation of clinical findings and oxygen saturation (SpO₂) values is present, although it is not particularly strong, with an overall correlation coefficient of -0.4 .^{60,286} This suggests that the use of oximetry may identify infants with reduced oxygenation that is not apparent clinically, and it should be one tool used in the assessment of need for hospitalization. In contrast, the rates of hospitalization and length of stay may inadvertently be increased by the use of oximetry.²⁴⁷ Current recommendations suggest that persistent measurements of SpO₂ of less than 90% may indicate the need for initiating supplemental oxygen.⁹ However, this recommendation is not based on any direct studies; therefore other values perhaps could prove to be better indicators of the need for oxygen support.

A Cochrane report reviewed the results of nine controlled trials comparing chest physiotherapy (vibration and percussion techniques) to no intervention among hospitalized, nonintubated patients with acute bronchiolitis. No differences were detected between groups in respiratory rates, oxygen requirement, length of stay, or severe side effects.²¹¹ In addition, deep pharyngeal or tracheal suctioning has not been shown to be beneficial.⁹

Conflicting results have come from trials evaluating the role of hypertonic saline inhalation for acute bronchiolitis. Results from some studies suggest a modest reduction in the length of hospitalization among patients treated with nebulized 3% saline versus those treated with 0.9% saline,^{14,235} but studies in which predefined endpoints (as opposed to randomly determined discharge times) have not demonstrated any benefit of hypertonic saline.^{85,253}

Several randomized trials have evaluated the usefulness of inhaled helium-oxygen therapy among children with bronchiolitis. This approach is based on the theory that helium-oxygen mixtures may improve gas flow through the high-resistance airways that characterize bronchiolitis.¹⁶⁵ A Cochrane review of published studies concluded that helium-oxygen therapy may have an early, transient benefit but does not result in a reduced rate of intubation, less mechanical ventilation, or shortened length of stay in a pediatric ICU.¹⁸²

The use of bronchodilating agents in the management of infants with RSV lower respiratory tract illness has varied considerably among centers in the United States and other countries.²⁸⁵ Bronchodilators have been administered to an average 75% to 80% of infants hospitalized with RSV infection.³¹² Trials evaluating α -adrenergic or β -adrenergic bronchodilating agents have given inconsistent results.¹⁶² The patients studied have varied in age, presence of underlying conditions, and history of previous episodes of wheezing, rendering comparisons somewhat difficult to make. A Cochrane review of bronchodilator therapy concluded that a limited transient improvement in assessment scores may be observed in one of every seven children treated, but the degree of improvement was minimal.¹⁶² A second Cochrane review of bronchodilator therapy for hospitalized infants and young children with bronchiolitis found no effect on oxygen saturation or length of stay. Outpatient bronchodilator treatment did not reduce the rate of hospitalization or reduce time to resolution of illness at home.⁹⁶ The American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis⁹ recommended that for management of infants with a first episode of wheezing, bronchodilators should not be used routinely. The guidelines note that a carefully monitored trial of inhaled α -adrenergic and β -adrenergic agents was a possible option in some cases. However, bronchodilator administration should be continued only if benefit was documented by objective means of evaluation. Anticholinergic medications alone or in addition to bronchodilatory agents have not been shown to improve the course of viral bronchiolitis.⁹

Numerous publications evaluating the effects of corticosteroids in bronchiolitis have appeared, with variable results. More recently, a study involving 20 emergency departments over the course of three RSV seasons examined the outcomes of 608 children aged 2 to 12 months who presented with a first episode of bronchiolitis in a double-blind, placebo-controlled trial that administered one dose of oral dexamethasone of 1 mg/kg.⁶⁶ The rate of hospitalization and the Respiratory Assessment Change Score (RACS) of these groups did not differ significantly. Furthermore, no benefit was observed among the subgroup of children with asthma or with a family history of asthma. The results of other original studies and a meta-analysis are in agreement.⁶⁸ The American Academy of Pediatrics guidelines⁹ concluded that current data do not support a recommendation for using corticosteroid therapy to prevent hospitalization, nor should corticosteroid medication be used routinely in the management of inpatient bronchiolitis. Some evidence exists that older children and those with prior episodes of wheezing and with asthma may potentially benefit from the administration of systemic glucocorticoid therapy.²²⁷

Montelukast is a selective leukotriene receptor antagonist that inhibits the cysteinyl leukotriene 1 receptor and is a modestly effective treatment for asthma and allergic rhinitis.^{28,56} Because increased leukotriene levels are present in nasal secretions during many viral infections, including RSV,^{69,277} montelukast was evaluated for its effectiveness in RSV lower respiratory tract disease. Although an initial controlled trial suggested a beneficial effect in infants with RSV bronchiolitis,²⁷ a large follow-up study randomizing 979 subjects failed to show a difference between the groups in the primary outcome (days with no cough, wheeze, or shortness of breath).²⁶

In developed countries, pulmonary bacterial superinfection is an unusual occurrence among children with RSV lower respiratory tract disease, and the administration of antibiotics in placebo-controlled trials has not been associated with beneficial outcomes.^{190,262} Moreover, prolonged administration of intravenous broad-spectrum antibiotics may augment the rate of secondary bacterial infection.¹⁵³ Antibiotics presumably should not be administered prophylactically to children with RSV infection or as therapy unless clear indications of the coexistence of a bacterial infection are present.

The only specific treatment currently approved for children hospitalized with RSV infection is ribavirin (1- β -D-ribofuranosyl-1H-1,2,4-triazole-3-carboxamide). This synthetic nucleoside has been administered as a small-particle aerosol for 12 to 22 hours per day until clinical improvement is evident, usually about 3 days. Much shorter, intermittent courses of higher doses also appear to be an acceptable mode of administration.⁹⁰ Although aerosolized ribavirin therapy has been

associated with a small but statistically significant increase in oxygen saturation during the acute infection in several small studies, a consistent decrease in mortality, need for mechanical ventilation, decrease in length of stay in the pediatric ICU, or reduction in days of hospitalization among ribavirin recipients has not been demonstrated. The need for specialized nebulizers to deliver the drug, concern about potential toxic effects among exposed health care personnel, unconvincing results of efficacy trials, and extremely high cost have led to infrequent use of this drug.⁹ Ribavirin is not recommended for routine use but may be considered for use in immunocompromised patients with documented, potentially life-threatening RSV infection, although it is not licensed for this indication.^{249,273}

Other compounds continue to be investigated for their possible therapeutic benefit in RSV infection. Polyclonal neutralizing antibodies against RSV have been shown to have no therapeutic effect.¹⁰⁹ Palivizumab, a monoclonal antibody against the RSV fusion protein, has been demonstrated to have an antiviral effect when used therapeutically in infants with RSV infection, but no clinical benefit has been demonstrated.¹⁸⁸ A small randomized controlled trial of motavizumab, another monoclonal antibody, also failed to demonstrate any therapeutic benefit.¹⁷¹ A complementary, antisense sequence of RNA (a short interfering RNA) that suppresses expression of the RSV nucleocapsid gene has been evaluated in adult volunteers who received the drug intranasally before RSV inoculation. No significant differences in the symptom scores between treatment and placebo groups were noted.⁷⁵ This compound was also investigated among lung transplant recipients for whom RSV lower respiratory disease may be fatal, but no positive effect was observed.³⁰⁸ Another promising area of investigation is inhibitors of RSV fusion. Inhibition of enzymatic activity associated with several epitopes within the fusion (F) RSV glycoprotein prevents viral entry into the host cell as well as inhibition of cell-to-cell spread.³¹⁰ Two fusion-inhibiting drugs have been studied in adult volunteers experimentally challenged with RSV intranasally. Each compound was able to reduce the degree of viral replication and the magnitude of symptoms following RSV challenge.^{76,77} It should be noted that, in each case, antiviral therapy was instituted before subjects developed symptoms following challenge. It remains possible that fusion inhibitors may have beneficial effects when started after symptoms appear, but this remains to be seen. Other small-molecule compounds that bind specific epitopes on viral-encoded proteins, including G, L, N, and P proteins, interfere with the viral replication cycle.⁵⁸ Clinical efficacy of these compounds has not yet been demonstrated.

PREVENTION

Breastfeeding

Most studies evaluating the protective effect of breastfeeding against RSV infection show a diminished likelihood of acquiring more severe infection.^{16,223} Although colostrum and breast milk contain IgG and IgA antibodies and neutralizing activity against RSV, the exact mechanism of the protective effect is unknown. Other possibly protective factors include multifunctional components in human milk.²⁰⁹ Longer term protection from breast milk against bronchiolitis may relate to human milk factors that modulate the infant's developing immune system.⁴¹ The degree and duration of breastfeeding necessary to provide protection against RSV infection remain undefined.¹⁷⁰

In a meta-analysis, infants who were exclusively breast-fed for 4 months were almost three times less likely to be hospitalized for lower respiratory tract disease (risk ratio, 0.28). It was estimated that 30% of hospitalizations of infants for infection would have been avoided for each additional month of full breastfeeding beyond 3 months.²²³ The authors thus estimated that if all 4-month-old infants had been exclusively breast-fed, 56% of hospital admissions for infants in the first year of life would have been prevented. This number seems unrealistic, possibly because many breastfeeding studies do not control for other factors that can influence the rate of hospitalization for RSV.

Infection Control and Nosocomial Infection

Infection control procedures in the home should focus on interrupting the spread of RSV by using effective hand hygiene practices, including

frequent hand washing or the use of hand sanitizers.³⁷ If hands are not visibly soiled, alcohol-based sanitizers are preferentially recommended.³⁷ Objects contaminated with respiratory secretions, which act as fomites, should be cleaned and used tissues discarded carefully.

Within medical settings, infection control procedures are the mainstay of controlling nosocomial infections from RSV.³⁷ More than 70 years ago, in 1941, Adams⁴ described an epidemic of pneumonitis that occurred in January through February in the nurseries of two Minneapolis hospitals. Thirty-two infants, mostly in the second and third months of life, were affected, and 29% died. Cytoplasmic inclusions in the bronchial epithelium were observed in all fatal cases. The distinctive epidemiology, clinical syndrome, and pathology of these cases led Adams to propose a viral origin. Twenty years later, he and his colleagues described a markedly similar epidemic of respiratory illness in infants in whom they identified RSV as the cause.⁶ RSV was thus implicated as the agent of the earlier, first-described nosocomial outbreak.

During community RSV epidemics, the risk for the nosocomial spread of RSV infection is high and, if not recognized, may result in prolonged hospitalization of infants and even increased mortality.¹¹⁸ The risk for acquiring nosocomial infection is related to the child's age, underlying disease, and length of hospitalization.

Among immunocompromised children and adults, nosocomial RSV infections often are serious and difficult to control. Outbreaks in transplantation units in particular have been associated with a high mortality rate and prolonged and intermittent transmission.^{35,91}

RSV infection frequently is introduced to the ward by hospital staff, families, and visitors who may have only a mild cold. Genetic analysis has demonstrated that nosocomial outbreaks may be caused by one or multiple strains of RSV during a single outbreak or season.^{16,205,259} Infection rates may be high among staff members, who often require absence from work.

Various infection control procedures have been employed to prevent the nosocomial spread of RSV (Table 182.3). Integral to any effective infection control program are assiduous hand hygiene and education of health care personnel, as well as families and visitors, including frequent reminders to ensure compliance throughout the RSV season.³⁷ Careful and continued education regarding the importance of infection control practices has reduced the incidence of nosocomial RSV infection in many pediatric facilities. These practices generally include (1) early identification of RSV-infected patients through laboratory screening of symptomatic patients, (2) cohorting of infected patients and staff, (3) excluding visitors with current or recent respiratory tract infections, (4) excluding staff with respiratory tract illness from caring for susceptible infants, (5) emphasizing hand hygiene before and after direct patient contact or contact with objects in the vicinity of patients, and (6) limiting visitation by young siblings and other young children during the RSV season.⁹ The efficacy of additional barrier precautions such as gowns, gloves, and masks has varied in different settings. In two controlled studies, the routine use of gowns and masks did not add further benefit to conscientious hand washing and other infection control procedures.^{139,207} With widespread application of infection control practices, the occurrence of nosocomial RSV infection in neonatal ICUs has become an uncommon event.²⁴

As many as 70% of RSV infections on hematology-oncology wards are nosocomial.^{2,55} More severe RSV disease is recognized to occur early after transplantation and among patients with persistent lymphopenia, chronic graft-versus-host disease, and allogeneic stem cell transplantation.^{11,55,79,150} Application of hand hygiene measures in conjunction with a private room, central HEPA-filtered air supply, and positive-pressure ventilation has been shown to significantly reduce RSV transmission on an oncology ward.¹⁷³

Prophylaxis

Interest in immunoprophylaxis against RSV infection for high-risk infants came from the observation that although maternally derived RSV antibodies may not completely protect against RSV disease in young infants, the severity of RSV lower respiratory tract disease was inversely correlated with neutralizing antibody titers. Subsequent trials with an enriched RSV immune globulin preparation (RSV-IVIG) demonstrated statistically significant differences in hospitalization rates

TABLE 182.3 Infection Control Procedures, Both Standard Precautions and Contact Precautions for Prevention of Respiratory Syncytial Virus Infection, Recommended by the Centers for Disease Control and Prevention

Category I-B Recommendations ^a	Comment(s)
Hand washing	Water with soap or antibacterial agent or waterless antiseptic hand rub
Wearing gloves	Combined with hand washing before and after each glove change; may diminish self-inoculation
Wearing gowns	When direct contact with patient or patient secretions is likely
Wearing masks and eye protection	Eyes and nose are major sites for inoculation
Housing patient in private room or in a cohort isolated from other patients	Patients with documented infection can be grouped and isolated from other patients; beds should be separated by >0.9 m
Use of dedicated patient care equipment sometimes recommended with less or no supporting evidence	Equipment, including toys, assigned to specific patients
Staff assigned according to patient's RSV status	Specific staff care only for patients with RSV infection
Visitor restrictions during RSV season	Some qualify by restricting young children only
Screening visitors for illness during RSV season	Visitor assessed by trained personnel or advised by use of an educational patient information list

RSV, Respiratory syncytial virus.

^aCenters for Disease Control and Prevention I-B recommendations based on "strong rationale and suggestive evidence" and strongly recommended for all hospitals and "reviewed as effective by experts in the field."

Modified from Hall CB. Nosocomial respiratory syncytial virus infections: the "cold war" has not ended. *Clin Infect Dis*. 2000;31:590-596.

between RSV-IVIG recipients and control groups, and the compound was licensed for clinical use in infants with risk factors for severe RSV disease.²⁴⁰ Standard IVIG preparations lacking high-titer RSV antibodies were less effective. Disadvantages associated with RSV-IVIG included the need for intravenous access, the risk for infectious disease transmission associated with plasma-derived products; supply issues; interference with live, attenuated vaccines; and most important, a significantly increased rate of adverse events when used in children with cyanotic congenital heart disease. These issues led to the development of monoclonal antibodies that can be administered in smaller volumes, and RSV-IVIG is no longer available.

In 1998, the US Food and Drug Administration (FDA) licensed a monoclonal anti-RSV antibody preparation, palivizumab, which targets a highly conserved epitope on the RSV F glycoprotein. Palivizumab was 50 to 100 times more effective than the polyclonal immunoglobulin, and the smaller volume administered circumvented many of the difficulties and adverse effects of use of a larger intravenous dose.^{149,224} Palivizumab was modified from a mouse monoclonal antibody recognizing a protective epitope of the RSV fusion glycoprotein. Only the antigen-binding site from the mouse monoclonal antibody was inserted into the spine of a human antibody, thus diminishing the chance of allergic reactions to the mouse-raised antibody. A randomized, multicenter, double-blind, placebo-controlled trial involving 1502 premature infants with or without chronic lung disease demonstrated that monthly intramuscular injections of palivizumab reduce the overall incidence of RSV hospitalization by 55% compared with placebo recipients.¹⁴⁹ A second randomized, placebo-controlled trial involving 1287 infants with

hemodynamically significant congenital heart disease published in 2003 confirmed the safety and efficacy of immunoprophylaxis in high-risk infants and young children.⁸⁹ The rate of hospitalization for RSV illness was reduced by approximately 50% among the infants who received prophylaxis in comparison with the placebo group. In different subgroups, the reduction of RSV hospitalization rates ranged from 39% to 78%, with the lower rates of protection observed among infants with chronic lung disease and congenital heart disease. Postlicensure studies suggested that reduction rates in the necessity for hospitalization with RSV infection may be even greater.¹⁰

A second-generation humanized IgG1 monoclonal antibody (motavizumab) derived by *in vitro* affinity maturation of the complementarity-determining regions of the heavy and light chains of palivizumab demonstrated approximately 18-fold greater neutralizing capacity than palivizumab.¹ Motavizumab was evaluated in a randomized, double-blind, noninferiority trial to palivizumab in 6635 infants with prematurity and/or chronic lung disease of prematurity. Motavizumab proved to be noninferior to palivizumab in terms of reduction in RSV hospitalization rates.⁴⁸ However, because of several concerns, including an increased incidence of hypersensitivity reactions among motavizumab recipients, motavizumab was not licensed by the FDA. Other monoclonal antibody preparations are now being studied in infants.

The mechanism by which RSV-neutralizing monoclonal antibodies interrupt the viral replicative cycle appears to be through inhibition of viral cellular fusion. Pretreatment of virus with either palivizumab or motavizumab does not inhibit the ability of the F protein to interact with the target cell receptor, but viral replication does not occur. This suggests these antibodies block virus-to-cell fusion, perhaps by preventing conformational changes in the F protein after attachment.¹⁷¹

RSV isolates resistant to palivizumab due to mutations in the palivizumab-binding site on the F protein initially were described *in vitro* during long-term incubation of infected cells in the presence of antibody.^{74,309,311} Subsequent reports have isolated palivizumab-resistant RSV isolates from RSV infected children who were receiving palivizumab prophylaxis.⁵ Palivizumab-resistant RSV isolates appear to account for only a subset of RSV cases occurring among infants receiving palivizumab. These escape mutants appear to have impaired growth characteristics relative to wild-type RSV. The importance of these escape mutants as a cause of breakthrough disease is poorly understood, but does not seem substantial.²⁷⁵

Current Guidelines for Immunoprophylaxis

Palivizumab is the only licensed product available to reduce the risk for RSV lower respiratory tract disease in infants and children, particularly those with underlying risk factors for more severe RSV disease. The American Academy of Pediatrics recommends prophylaxis for subgroups of high-risk children for different periods of time depending on their gestational and postnatal ages, the severity of their underlying conditions, their need for recent medical therapy, and the presence of other risk factors. Prophylaxis with palivizumab is recommended for otherwise healthy infants who were born at less than 29 weeks, 0 days of gestation. Palivizumab is also recommended for infants in their first year of life who have chronic lung disease (essentially bronchopulmonary dysplasia [BPD], using the definition of a requirement for supplemental oxygen through the first 28 days of life), and again in their second year of life if they continue to require medical therapy (largely oxygen) for BPD within 6 months of the onset of the RSV season.^{10,9}

Palivizumab is administered intramuscularly at a dose of 15 mg/kg once every 30 days throughout the RSV season. For most areas of the United States, monthly prophylaxis should begin in November, but knowledge of local epidemiologic patterns can help in making a more informed decision.^{10,9} After a child has qualified at the beginning of the season for the administration of prophylaxis, it should be continued until the epidemic season ends, but with no more than five monthly doses.¹⁰ These guidelines have been contested, largely because they oppose the initial FDA guidelines established as a result of the initial clinical trials that led to the approval of palivizumab and because the changes are not based on newer, controlled trials.³⁰⁴

The use of palivizumab in itself remains controversial. Economic analyses, in general, have not demonstrated an overall savings in health

care costs if all high-risk children receive prophylaxis.^{80,237} Cost-benefit analyses have been difficult to complete because of considerable geographic variation in hospitalization costs for such infants. Most published cost-effectiveness analyses have found that the cost of immunoprophylaxis exceeds the economic benefit of avoiding an RSV hospitalization.^{132,287,306} Palivizumab immunoprophylaxis has not reduced mortality for infants with RSV infection in any study, although this may be difficult to accomplish because the mortality rate from RSV currently is very low. An effect of palivizumab prophylaxis on short-term wheezing has been suggested in some studies,^{30,305} but not longer-term studies,²¹⁶ and no firm conclusions on the strength of this effect can be drawn currently.

Vaccines

Control of RSV has long lured but eluded investigators. Although the outcome of infants with RSV infection has improved greatly in recent years, the burden on health care that RSV imposes yearly remains notable among both children and adults.²²⁸ Immunoprophylaxis with palivizumab administration will lower the RSV hospitalization rate among high-risk infants and young children, but the vast majority of hospitalized young children do not have risk factors that justify the use of palivizumab. Thus immunoprophylaxis will have only a modest impact on the overall burden of RSV disease in the United States. Only effective immunization is likely to alleviate this burden. Certain characteristics of RSV infection, however, continue to pose barriers to the successful development of a vaccine.

The shroud of past experience with the formalin-inactivated vaccines has conferred caution and concern regarding the development of candidate vaccines. The initial RSV vaccine trials, with the alum-precipitated, formalin-inactivated vaccine (FI-RSV), were conducted in 1966 to 1967 among seronegative children 2 months or older with the administration of an inactivated and trivalent parainfluenza vaccine. When naturally infected during the subsequent RSV outbreak, the FI-RSV vaccinees experienced an unanticipated increased severity of disease. Almost 80% required hospitalization, and two died.^{59,95,158} The unfortunate outcomes of these trials stimulated research that has been integral to the evolution of future vaccines. Subsequent examination of the vaccinees' immune response and experiments in rodent models with exaggerated disease indicated that the formalin-inactivated vaccine produced a poor and defective neutralizing antibody response and mild peripheral blood and pulmonary eosinophilia (not observed in human disease), perhaps suggesting an excessive Th2-type CD4 T-cell response.^{95,158,164} These studies suggested that a successful vaccine should evoke a balanced immune response with both CD4⁺ and CD8⁺ cytotoxic lymphocytes (see [Immune Response: Immunity and Disease Pathogenesis](#)).^{113,193}

An RSV vaccine should reflect the immune response of natural infection, yet improve its inconsistent and nondurable protection. In addition, an RSV vaccine would need to be administered in the first few weeks of life, when the most severe disease usually occurs. Little experience exists regarding immunization with live viruses during the neonatal period when the immune system is incompletely developed and interfering maternal antibody is present.²¹⁸ However, pregnant women respond well to vaccines with resulting placental transfer of maternal antibodies during the third trimester, which may be a potential approach to offer protection to infants early in life. Furthermore, the effect of the multiple antigens from other vaccines administered in the first few months of life must be considered.

Vaccine development subsequently has cautiously taken several approaches with production of live, attenuated, protein subunit, and vectored candidate vaccines. Protein subunit vaccines have raised concern for disease enhancement, particularly in the pediatric population, and thus trials have been largely restricted to older children and adults. Candidate subunit vaccines have used primarily the two major surface glycoproteins, F and G, which are the major targets for the production of neutralizing antibodies.⁶⁷ Clinical investigation has focused on vaccines of the F protein, which has greater cross-reactivity between RSV A and RSV B strains. Three generations of purified F protein vaccines, PFP-1, PFP-2, and PFP-3, which consist of immunoaffinity-purified, alum-adsorbed F glycoprotein, have been evaluated in clinical trials. The initial PFP-1 vaccine contained small amounts of the G protein, which did induce an antibody response. PFP-1 and PFP-2 vaccines have been

administered to normal adults, institutionalized adults, normal children, and individuals with chronic underlying conditions including chronic lung disease, cystic fibrosis, and asthma.^{107,108,222}

The PFP vaccines generally were safe and modestly immunogenic. The PFP-2 vaccine, administered during the third trimester in a study of maternal immunization, showed no adverse effects on the infants. At delivery, only low levels of maternal neutralizing antibody were present in the infant. However, increased levels of IgG, but not IgA, antibody to the F protein did occur in breast milk. A meta-analysis of the PFP vaccine trials concluded that a significant relative risk of 0.55 (95% confidence interval, 0.35–0.88) in the overall number of RSV infections existed, but the heterogeneity of the studies cast doubt on the validity of this conclusion. Vaccination with PFP did not show any effect on reducing the incidence of RSV lower respiratory tract disease.²²²

Numerous nonreplicating vaccines, including other protein subunits of the G and F proteins and DNA vaccines have been developed, and some are in stages of development at the present time. DNA plasmid vaccines expressing F or G glycoproteins have shown limited immunogenicity.^{21,181} Nanoparticle vaccines have interesting properties that may prove advantageous in vaccine development.¹⁷⁷ One of these vaccines is now in phase III trials in a maternal immunization protocol. Licensing of these vaccines is not likely for at least 5 years.

Live, attenuated vaccines have the advantage over subunit vaccines of producing an immune response that more closely mimics the natural route of inoculation into the upper respiratory tract, thus eliciting more balanced local and systemic humoral and cellular responses and offering potentially broader and more durable protection. The initial live, attenuated candidate vaccines were derived from cold-passaged mutants propagated from wild-type RSV (wt RSV) strains grown at progressively lower temperatures, and strains were selected by growth at low temperatures, similar to that of the upper respiratory tract. Subsequent passage in the presence of chemical mutagenic agents produced candidate strains that were temperature sensitive (*ts*) and unable to replicate at the higher body temperatures of the lower respiratory tract.³⁰¹ These candidate (*cp* and *ts*) vaccines were tested in adult volunteers and seropositive children without complication but proved to be unsuitable for infants and young, seronegative children.^{159,160} These vaccines were associated with unacceptable degrees of illness, were overattenuated and not protective, or were genetically unstable; some were accompanied by prolonged shedding of wild-type virus, which most frequently was observed in infants and resulted in transmission of the shed virus to 20% to 25% of the unvaccinated contacts.¹⁵⁹

More recent vaccine candidates have been derived from previously combined *cp* and *ts* (*cpts*) mutants, which contain mutations generated by reverse genetics that allow the precise desired enhancements of stability, attenuation, and immunogenicity. For example, one candidate, *cpts* 248 strain, was further mutated and attenuated into *cpts* 248/404. Each of its mutations was introduced alone or in combination into wt RSV for evaluation in experimental animals of the mutations' immunogenic and attenuating effects. This candidate *cpts* 248/404 vaccine was immunogenic in seropositive and seronegative children older than 6 months, but upper respiratory tract illness with appreciable nasal congestion developed in younger infants 1 and 2 months of age.¹⁶⁰ These vaccines are not being further developed presently.

Reverse genetics has produced a lineage of further “designer gene” candidate vaccines with one or combined deletions of *NS1*, *NS2*, *M2-2*, and *SH* genes.^{159,256} Of these, the *M2-2* is undergoing the most intensive investigation currently.¹⁶⁰

Novel adjuvants also are being developed, some of which can shift the immune response evoked by subunit vaccines from a Th2- to a Th1-type response in experimental animals. Enhanced immunogenicity appears possible with enterically active adjuvants and carriers, such as liposomes and biodegradable microspheres, and with adjuvants in vesicles of immunostimulating complexes.⁶⁷

A third approach to vaccine development involves engineered live viral vectors, including vaccinia virus, adenovirus, Sendai virus, and parainfluenza virus. Results from animal models indicate that these vaccines are immunogenic, but antibody responses in human children have been minimal.²⁰¹

Human Metapneumovirus

183

Jennifer E. Schuster • John V. Williams

Human metapneumovirus (MPV, HMPV) is a paramyxovirus that is a ubiquitous respiratory tract pathogen with seropositivity demonstrated in virtually all adults around the world.* The spectrum of disease varies from minor upper respiratory tract illness to lower respiratory tract disease, with significant morbidity and mortality.^{68,220,233,248} The clinical manifestations of MPV include bronchiolitis, croup, pneumonia, asthma exacerbations, and acute otitis media, similar to other common respiratory viruses. MPV can cause severe disease in children and adults with underlying medical conditions as well as in older adults.[†] Multiple epidemiologic studies have demonstrated that MPV is widely prevalent and is usually second to respiratory syncytial virus (RSV) in incidence.^{67,68,165,167} Research groups have begun to elucidate the pathogenesis and immunity of MPV, thereby facilitating the development of preventive strategies and vaccines.

HISTORY

In 2001, van den Hoogen and colleagues²²⁰ discovered a novel virus in respiratory specimens collected from 28 Dutch children with acute respiratory illness over a 20-year period. Clinical symptoms were similar to those of RSV, and disease severity ranged from mild respiratory infection to respiratory failure requiring mechanical ventilation. The unknown virus produced cytopathic effects, including syncytia, in monkey kidney cells. However, the polymerase chain reaction (PCR) result for known respiratory viruses was negative, and the virus did not adsorb red blood cells (hemagglutination). Elegant random reverse-transcriptase (RT)-PCR experiments provided sufficient genomic sequence data to place the virus in the Pneumovirinae subfamily of the Paramyxoviridae (*Pneumoviridae* have now been classified as a separate family within *Mononegavirales*). MPV, like avian metapneumovirus (AMPV), is a member of the *Metapneumovirus* genus, but it is the first described human pathogen in the genus. The virus most closely related genetically to MPV is avian metapneumovirus type C (AMPV-C); evolutionary analyses of viral genes estimate that MPV diverged from AMPV-C 200 to 300 years ago.^{48,255} MPV-specific antibodies were present in human sera from 1958,²²⁰ a finding confirming that the virus circulated before recent identification.

PROPERTIES

Structural and Antigenic Properties

MPV contains a single-stranded, negative-sense RNA genome with a lipid envelope, as do all paramyxoviruses.²²⁰ MPV lacks the two nonstructural proteins, NS1 and NS2, encoded by RSV (Fig. 183.1). The eight genes are nucleoprotein (N), phosphoprotein (P), matrix protein (M), fusion protein (F), second matrix protein (M2), small hydrophobic protein (SH), and polymerase protein (L). The M2 gene has two open reading frames, M2-1 and M2-2, for a total of nine viral proteins. The gene order in MPV (3′N-P-M-F-M2-SH-G-L-5′) demonstrates a different placement of the F and M2 genes compared with RSV (3′NS1-NS2-N-P-M-SH-G-F-M2-L-5′). The absent nonstructural proteins and the different gene order characterize MPV as a member of the *Metapneumovirus* genus.^{219,220} Like all pneumoviruses and paramyxoviruses, the fusion protein is synthesized as an active precursor cleaved by host proteases.²¹⁹ The fusion protein binds to integrins, which serve as entry receptors, as well as heparan sulfate.^{29,39,41} Entry occurs by multiple mechanisms, including membrane fusion with endosomes.⁴⁰

Electron microscopy demonstrates paramyxovirus-like pleomorphic spherical, and filamentous particles 150 to 600 nm in size, with short envelope projections of 13 to 17 nm representing glycoprotein spikes.^{170,220} Nucleocapsid diameter averages 17 nm.¹⁷⁰ The genome is about 13.3 kb in size.^{15,172,219} Sequence analysis demonstrates that MPV is most similar to AMPV-C, with six of the nine proteins having a 70% to 80% amino acid identity with AMPV-C.^{172,219} The SH and G proteins are the most divergent between the two viruses, as well as among MPV genotypes.^{15,219} The F protein is highly conserved with 93% to 97% amino acid identity among all strains of MPV.^{15,20,222,255} Phylogenetic analysis of MPV genes identifies four distinct genetic lineages.^{12,20,48,222,255} These lineages are classified into two groups (A and B), each with two subgroups (A1, A2, B1, and B2). Further subdivision of A2 into A2a and A2b has been proposed but not confirmed.⁹⁵ All four strains have been identified in different global regions over multiple years, a finding demonstrating that they are not exclusive to countries or seasons.

Most evidence suggests that the different genetic lineages of MPV do not represent distinct serotypes. Animal studies in rodents and nonhuman primates show a high degree of cross neutralization and cross protection among subgroups,^{139,204,214} although one study in ferrets identified a 16-fold difference in serum neutralizing antibody titer.²²²

FIG. 183.1 Genomic map of human metapneumovirus compared with human respiratory syncytial virus. The putative open-reading frames and the approximate nucleotide positions within the genome are indicated.

Laboratory Growth

MPV requires trypsin for optimal replication in most cell types and is difficult to culture.²²⁰ LLC-MK2 and Vero cells, two monkey kidney epithelial cell lines, are the most permissive, with viral replication enhanced by supplemental trypsin.²¹⁵ A low level of replication occurs in LLC-MK2 and MA-104 cells without trypsin, and some strains exhibit a reduced dependence on trypsin.¹⁹⁰ No growth is observed on MDCK or CEF cells even with exogenous trypsin.^{170,220} In LLC-MK2 cells, plaques tend to be small and round with occasional syncytia.^{17,170} Cytopathic effects are noted between 3 and 23 days (average, 17 days).¹⁷ The subtle, late cytopathic effects in primary isolates and trypsin requirement likely account for the failure to detect MPV previously.

Animal Susceptibility

Van den Hoogen and colleagues^{119,220} infected turkeys, chickens, and cynomolgus macaques with MPV. No overt clinical symptoms were observed in the birds, but one-half of the monkeys exhibited upper respiratory tract disease. Viral replication was not detected in poultry but was present in all macaques.²²⁰ African green monkeys appear to be the most permissive nonhuman primate species.²⁰⁴ Fatal MPV infections have occurred in wild chimpanzees and gorillas, as well as in zoologic facilities, likely transmitted from humans based on sequencing of the isolates.^{107,118,162,206} Hamsters, ferrets, cotton rats, and several strains of inbred mice display viral replication in the upper and lower respiratory tract, thus allowing for small animal models.^{139,246,253} Cotton rats displayed the highest lung viral titers, whereas Syrian golden hamsters had the highest nasal titers.²⁴⁶ Ferrets and guinea pigs have been infected for generation of antisera but do not manifest clinical symptoms.²²⁰

EPIDEMIOLOGY

Geographic Distribution

Epidemiologic studies have verified the presence of MPV worldwide. The incidence of the virus varies among countries and years, but MPV circulates in every year.*

Seasonal Patterns

In temperate regions, MPV is present during most of the year but peaks in late winter-early spring, typically following peak RSV incidence.[†] In subtropical climates such as Hong Kong, a spring-summer season similar to that seen with RSV occurs.¹⁶⁷ Biannual peaks of seasonality have been described in some European studies.¹⁸⁵ In general, rates of MPV acute respiratory infection are lower than RSV and comparable to parainfluenza and influenza,^{31,92,101,125,155,167,207} although MPV does on occasion surpass RSV in incidence.¹¹⁰

Strain Variation

The predominant subtype varies by site and year.^{74,109,160,195,207,248} In Italy, the incidence of MPV varied from 8% to 20% over a 3-year period. All four subtypes were identified each season; however, the predominant subtype changed. In 2001 to 2002, A1 accounted for 59% of all strains, the following year B1 and B2 were present equally, and in 2003 to 2004, 72% of strains were A2.⁷⁴ Similar variation was observed in a 20-year prospective US study, with multiple genotypes present in most years.²⁴⁸ In recent years, A1 has not been identified in multiyear studies in diverse regions.^{137,156,164,195} Whether groups and subgroups differ in virulence

remains unclear. Vicente and colleagues²³¹ reviewed MPV strains isolated in Spain and noted that children with group A infection had significantly more frequent pneumonia and higher disease severity. Similarly, Jordanian children with MPV A were more likely to require supplemental oxygen.¹⁹⁵ A Canadian study found that genotype B was associated with more severe disease in hospitalized patients.¹⁶⁵ In France, patients with group B strains were more likely to have abnormal chest radiographs, but they did not have significant differences in oxygen saturation, hospitalizations, or clinical severity scores.¹⁷¹ Other studies have found no major distinctions in disease severity,^{3,56,207} laboratory abnormalities,¹⁴⁹ or symptoms^{109,234} among genotypes. Group A viruses replicate more efficiently in animal models, a finding suggesting some meaningful biologic differences among groups.^{204,221}

Viral Load

The relationship between viral load and disease severity is unclear. Roussy and colleagues¹⁸⁶ noted that an MPV viral load 1000 copies per 10⁵ cells or larger was associated with hospitalization and use of adjunctive therapies, including corticosteroids and bronchodilators. Other studies have identified an association between higher viral load and fever, bronchodilator use, lower respiratory tract involvement, duration of oxygen therapy, need for hospitalization, and length of hospital stay.^{23,146,183} However, an association with viral load and disease severity has not been confirmed in all studies. In a large cohort of Jordanian children, viral load was not associated with supplemental oxygen use.¹⁹⁵ Similarly, viral load was not associated with disease severity in Kenyan children⁷¹ or with progression of disease in a hematopoietic stem cell transplant population.¹⁹⁹

Incidence and Prevalence

Many epidemiologic studies of MPV include convenience samples collected in single-center clinical settings from patients with acute respiratory infection and report incidence rates of MPV between 5% and 25%.* Some prospective and multicenter studies exist.

A prospective study of all hospitalized children younger than 18 years over a single winter in Hong Kong detected HMPV in 32 of 587 (6%), slightly less than the rate of 8% for both RSV and influenza. The estimated incidence of HMPV-associated LRI requiring hospitalization was four in 1000.¹⁶⁷ A systematic study of all lower respiratory illnesses in Queensland, Australia over 4 years detected HMPV in 707 of 10,025 (7%), with seasonal peaks of 15%; the rates of RSV and influenza in this cohort were 9% and 4%, respectively.²⁰⁷ A 25-year prospective study of children with acute lower respiratory illness in Tennessee identified MPV in 12% of all specimens.²⁴⁴ A large, population-based, prospective surveillance study in 2 United States cities found that the incidence of hospitalization for MPV in children younger than 5 years old was 1.2 per 1000, lower than the rate of RSV-associated hospitalization in the same cohort (three in 1000) but similar to the rates for influenza (0.9 in 1000) and parainfluenza virus type 3 (PIV-3) (0.5 in 1000).²⁴³ A prospective 1-year study of outpatient children with acute respiratory illness in Melbourne, Australia tested 543 specimens by RT-PCR and detected MPV in 6%, RSV in 7%, and influenza in 4%.¹²⁵ A prospective study that enrolled 878 hospitalized children during a winter in China detected HMPV in 26% and RSV in 36%.³⁰

Hospitalization rates from MPV are similar to those from other viruses, including PIV, adenovirus, rhinovirus, and influenza.^{92,144} Hospitalization rates vary annually similar to incidence rates. In a retrospective study of children in Utah, annual hospitalization rates varied from nine to 79 of 100,000 person-years.⁴⁴ Young infants typically

†References 56, 58, 66–68, 98, 101, 125, 160, 175, 195, 207, 220, 244, 248.

*References 4, 31, 56, 72, 101, 110, 125, 160, 167, 177, 207, 220, 244.

have the highest rates of hospitalization. In a prospective study of Jordanian children, hospitalization rates in children younger than 6 months exceeded seven per 1000 children in years with high MPV activity.¹⁹⁵ Over a 6-year prospective multicenter study in the United States, rates of MPV hospitalization in children younger than 5 years averaged one per 1000. Rates of outpatient clinic and emergency department visits in children younger than 5 years were 55 and 13 per 1000 children, respectively. In some years, outpatient visits in children 6 to 11 months of age exceeded 130 visits per 1000 children, a finding indicating a significant burden of outpatient disease.⁵⁸

A South African study of children hospitalized with acute respiratory infection found that MPV was present in 126 of 1409 (9%) and was the most common virus after RSV; the incidence of MPV-associated hospitalization in human immunodeficiency virus (HIV)-negative children was 29 in 1000.¹⁴¹ A Japanese 2-year, multicenter study of inpatient and outpatient children with acute respiratory infection identified MPV in 57 of 637 (9%), with many cases proven by serologic study to be primary infections.⁵⁶ A 5-year observational study of Korean children younger than 5 years found MPV in 24 of 515 (5%), similar to the rates for influenza and PIV-3.³¹ In Argentina, MPV was isolated from 11% of previously negative specimens in children with respiratory illnesses.⁷² In Jordanian⁴ and Israeli children,¹⁷⁷ MPV without coinfection caused 6% and 10% of acute respiratory infections, respectively.

Children hospitalized with MPV infection tend to be older than those admitted with RSV.^{18,31,101,153,160,167,220} In a prospective analysis of Chinese children with acute respiratory infection, MPV-infected children averaged 22 months of age compared with 10.5 months in children with RSV ($P < .001$).¹⁰¹ A male predominance has been observed in some studies but is not always statistically significant.^{31,66,101,167,243}

There are fewer studies of adults with MPV infection, but the rate of MPV in studies of adults with acute respiratory infection is 2% to 14%.^{60,68,79,102,233,240} A 4-year prospective study detected MPV in 8.5% (range, 4.4–13.2%) of adults hospitalized with acute respiratory infection.²³³ A population-based study found that the incidence of hospitalization with MPV in adults age 50 years or older was one per 1000, similar to the rates for influenza (1.2 in 1000) and RSV (1.5 in 1000).⁶⁰ In patients 18 to 49 years of age, hospitalization rates were about two per 100,000, although emergency department visits were 5 to 6 times more common.^{238,239}

MPV has been implicated in outbreaks in hospitals and long-term care facilities for adults and children, thus leading to mortality with rates as high as 25% in oncology patients or extremely old adults.^{19,91,97,124,148,157,216,256} Kim and colleagues¹¹¹ reported transmission of MPV to pediatric hematology-oncology patients during a nosocomial outbreak. Two children shared a room with an infected child. Standard, but not droplet, precautions, were used. The incubation period was between 7 and 9 days. In laboratory studies, virus has been isolated from metal and nonporous surfaces for up to 8 hours,²¹⁵ although another study suggests that drying of MPV resulted in loss of infective particles, whereas viral RNA could still be detected at day 7.¹⁵⁴ Because of the significant morbidity and mortality of MPV in high-risk children, isolation precautions are important.

Exposure to MPV is ubiquitous by adulthood. In one Dutch study, 100% of patients older than 5 years demonstrated a positive antibody response to MPV.²²⁰ Serosurveys testing large sample collections in Canada, China, Croatia, Germany, Israel, Japan, Taiwan, Thailand, the United States, and Uruguay showed that 95% to 100% of children have antibodies against HMPV by the age of 5 years.^{94,130,133,135,136,138,149,151,166,251} In many of these studies, 50% to 75% of children were seropositive by age 2 years, a finding suggesting that most children acquire primary HMPV infection early.

Hospitalizations from MPV have significant associated costs, varying widely by country.¹⁴⁴ The estimated median hospitalization cost exceeded \$5513 per child from a cohort of MPV-positive children in the United States from 2007 to 2013, with a median length of stay of 2.8 days.⁴⁴ Children with chronic medical conditions had significantly higher costs.

PATHOGENESIS AND PATHOLOGY

The pathogenesis of MPV has been described in animals and humans, although human data are limited. In macaques, the incubation period

was short, at about 2 days. Necropsy revealed mild erosive and inflammatory changes in the mucosa and submucosa of the airways. Alveolar macrophages were increased, and virus replicated in ciliated respiratory epithelial cells.¹¹⁹ In a mouse model, inflammatory infiltrates with a lymphocytic and monocytic predominance and perivascular edema were seen in the peribronchial areas. Histopathologic features peaked between days 5 and 7 with evidence of abnormalities remaining on day 14.¹¹⁶ Similar patterns of bronchiolitis were observed in the cotton rat model.²⁴⁶ Sumino and colleagues²¹¹ reviewed the lung pathologic features of five adults with MPV infection. Histopathologic findings in three patients demonstrated acute, organizing lung injury with diffuse alveolar membrane formation and the presence of smudge cells. The fourth patient had no evidence of lower respiratory tract infection, and the fifth patient had nonspecific acute and chronic inflammation. A similar study in children revealed chronic inflammatory changes of the airways with intra-alveolar macrophages.²²⁶ In a mouse model, depletion of alveolar macrophages was associated with milder disease, suggesting an important role for host inflammation in MPV pathogenesis.¹¹⁷ However, natural killer (NK) cells did not contribute to viral clearance or immunopathology in a murine model.²³⁷ A major limitation of the reports of human pathology is that the patients had been mechanically ventilated for a prolonged period before death, and thus it is impossible to distinguish virus-induced pathologic features from barotrauma and nonspecific inflammation.

The interaction between MPV and the immune system has been studied in humans and animal models, but the relationship is poorly understood. Laham and colleagues¹²² evaluated cytokines from nasal wash specimens of children with acute viral lower respiratory infections. Comparing MPV-infected with RSV-infected children, interleukin (IL)-12, tumor necrosis factor- α , IL-1 β , IL-6, and IL-8 were lower, but IL-10 was not different. Cytokine profiles of hospitalized versus outpatient children with MPV were not significantly different. Another study evaluated cytokine production induced by MPV in the lungs of mice. Interferon (IFN)- α and IFN- γ were present at higher levels than RSV, as well as granulocyte-macrophage colony-stimulating factor.⁷⁸ In peripheral blood mononuclear cells, MPV produced more IL-6 compared with RSV but less IFN- γ .⁵⁴ Mice lacking type 1 IFN responses are able to clear the virus and have less lung inflammation, a finding suggesting that type 1 IFN may contribute to MPV pathogenesis.⁸³ MPV lacks the genes that mediate innate immune inhibition in other paramyxoviruses. Nonetheless, MPV is capable of blocking type 1 interferon responses by an unclear mechanism; studies have implicated the G, M2-1, P, and SH proteins.^{11,50,76,82,115,117,129,179,180} MPV and other respiratory viruses induce functional impairment of lung CD8⁺ T cells, which fail to secrete IFN- γ or exhibit cytotoxic degranulation in response to viral peptides. This lung CD8⁺ T-cell impairment is primarily driven by programmed cell death-1 (PD-1) signaling and resembles CD8⁺ T-cell exhaustion induced by cancer and chronic infections such as with HIV and hepatitis C virus.^{62,63} These exhausted T cells remain impaired during challenge infection in an animal model, thereby suggesting a potential mechanism for the capacity of MPV to reinfect humans throughout life.⁶⁴

Humans mount robust antibody responses to MPV, and antibodies alone can protect in animal models. However, immunity likely wanes over time and provides limited cross protection among genotypes because recurrent infections in children and adults are well described,^{68,240} with genetically different strains,^{56,109,168,170,244} as well as with strains from the same lineage.²⁴⁸ In vitro, antisera show evidence of cross protection between A and B strains, with neutralization titer generally four-fold higher against homologous versus heterologous strains.²²² Using a mouse model, Kolli and colleagues¹¹⁶ demonstrated that initial infection with MPV was protective against reinfection 6 weeks later with a homologous strain. Early protection was confirmed in macaques; however, when these animals were challenged 12 weeks after initial infection, virus replication was detectable despite the presence of serum antibodies. At 11 months, antibody levels and protection had waned further; all macaques infected with heterologous virus and two of three macaques reinfected with homologous virus had no evidence of protection.²²¹ These data suggest that in primates, and likely humans, antibody levels wane over time, facilitating reinfection. A prospective study in humans noted that baseline MPV antibodies were lower in patients who

subsequently became infected versus those who did not become infected.⁶⁹ Thus, cross-protection and duration of antibody responses are important issues for vaccine development.

CLINICAL MANIFESTATIONS

MPV causes upper and lower respiratory tract disease, as well as systemic symptoms, although signs and symptoms vary in incidence among studies. Clinically, MPV causes symptoms similar to those of RSV and other respiratory viruses.^{18,56,155,244,257} Fever is present in the majority of cases.^{31,56,66,110,167,207,248} Transient maculopapular rash has been described in 8% to 12% of patients.^{110,167,207} Gastrointestinal symptoms are described with low frequency.^{56,167,244} Duration of hospitalization does not differ between children with RSV and MPV.^{18,167} White blood cell count and C-reactive protein are not significantly different between RSV and MPV.^{101,243} Similarly, abnormalities in transaminases are uncommon, although the previous study identified 27% of patients with alanine transaminase and aspartate transaminase values more than twice normal.¹¹⁰

MPV is rarely detected in asymptomatic persons,^{10,27,58,67,93,161,197,223,244} although in otherwise healthy young adults, MPV infection can be subclinical.⁶⁸ The duration of shedding in healthy individuals is approximately 7 to 14 days.^{56,121} However, symptomatic episodes with shedding in healthy persons for 3 weeks or longer have been reported,²⁷ and shedding in patients with hematologic malignant diseases is also prolonged.¹⁸⁴

Upper Respiratory Tract Manifestations

Rates of upper respiratory tract disease are less than lower respiratory tract disease.^{65,101,244,248} Hoarseness, laryngitis, sore throat, and croup are less common than pulmonary symptoms, although rhinorrhea is a frequent finding.^{31,56,101,167,207,243} One study in Nashville, Tennessee, detected MPV in 5% of children with upper respiratory disease, an incidence similar to that of RSV, influenza, and PIV but lower than adenovirus and rhinovirus. In that cohort, fever was present in 54% of patients, coryza in 82%, cough in 66%, pharyngitis in 44%, hoarseness in 8%, and conjunctivitis in 3%.²⁴⁸

MPV is associated with acute otitis media and has been isolated by nasal wash and tympanocentesis.^{158,191,212,244,247,248} Schildgen and colleagues¹⁹¹ isolated MPV in NP specimens from 13% of children with acute otitis media. Nokso-Koivisto and colleagues¹⁵⁸ noted that 24% of children with MPV and upper respiratory infection had acute otitis media; the incidence of acute otitis media was lower in children with MPV than in those with adenovirus, coronavirus, RSV, influenza virus, PIV, and rhinovirus. In a study of 118 children with MPV and upper respiratory tract infection, 63% had an abnormal tympanic membrane, although this was not significantly different from children with RSV, PIV, or influenza.²⁴⁸ Bacterial coinfection is common, but MPV has been isolated as the sole pathogen in middle ear fluid.²¹² In another study, children with MPV had a more common history of acute otitis media necessitating tympanocentesis compared with RSV.²⁵⁰ Peak MPV activity has been temporally associated with an increased number of visits and diagnoses of acute otitis media.²¹⁰ However, in a prospective study of 362 children, MPV was associated with symptomatic upper respiratory tract infection but not the development of acute otitis media compared with other viruses.³³

Lower Respiratory Tract Manifestations

Lower respiratory tract signs and symptoms include cough, wheeze, and rhonchi. In a cohort of Bangladeshi children, MPV accounted for 14% of all early childhood wheezing episodes.⁴⁵ In a large study of Chinese children with acute respiratory infection, wheezing was more common in children with RSV, but MPV-infected children were diagnosed with pneumonia more than were RSV-infected children: 47% versus 31% ($P = .002$).¹⁰¹ Conversely, a larger percentage of children with RSV were diagnosed with bronchiolitis compared with MPV: 62% versus 42% ($P < .001$). Other studies also note the trend toward a higher percentage of children with MPV and pneumonia compared with RSV,^{243,244} although this is not always statistically significant.¹⁶⁷ Jroundi and colleagues¹⁰³ noted that in Moroccan children with World Health

Organization–defined severe pneumonia, MPV was associated with more severity and a higher risk of intensive care need than RSV. MPV has been implicated as a cause of pediatric community-acquired pneumonia because it is detected significantly more frequently in children with community-acquired pneumonia than in healthy control subjects.^{182,197} MPV-associated community-acquired pneumonia requiring hospitalization was significantly more common in children younger than 5 years than in other age groups.⁹⁸ Frequency ranges of signs and symptoms of MPV infections in young children are presented in Table 183.1. As can be seen, the ranges vary considerably by feature in the studies reviewed. Presented in Fig. 183.2 is the chest radiograph of a child with MPV pneumonia.

TABLE 183.1 Signs and Symptoms in Young Children With Human Metapneumovirus Acute Respiratory Tract Infections

Clinical Feature	Frequency Ranges (%)
Acute otitis media	11–26
Asthma exacerbation	9–47
Conjunctivitis	3–9
Coryza	82–88
Cough	67–100
Crackles, rales	4–89
Cyanosis	2–85
Dyspnea	5–91
Febrile seizures	4–16
Fever	36–97
Pharyngitis, sore throat	10–46
Rash	4–13
Rhinorrhea	18–91
Tachypnea	59–81
Vomiting and/or diarrhea	0–54
Wheezing	15–56

Data from references 5, 9, 22, 30, 46, 52, 56, 101, 109, 110, 143, 167, 223, 244, 248, 249, 257.

FIG. 183.2 Chest radiograph of a child infected with human metapneumovirus demonstrating bilateral pneumonic infiltrates (arrows) and hyperinflated lung fields.

In one study, 75% of children with MPV had no underlying medical conditions¹⁸; however, in some cohorts, the majority of hospitalized MPV-positive children had a complex medical condition.⁴⁴ Although death is most commonly described in immunocompromised patients and in patients with underlying conditions, healthy children do have fatal sequelae of MPV. Donoso and colleagues⁵³ reported a case of a previously healthy 2-year-old child with fatal pneumonia, hypotension, and acute respiratory distress syndrome secondary to MPV. A similar case was reported in a 20-month-old male child with acute respiratory distress syndrome who developed multiorgan system failure with hepatitis, cytopenia, coagulopathy, and renal failure requiring extracorporeal membrane oxygenation.¹⁹³ In a cohort of pediatric intensive care unit (ICU) patients, children with MPV required a longer duration of mechanical ventilation than those with RSV (11 days vs. 7 days).⁵⁹ Spaeder and colleagues²⁰⁸ described a cohort of 111 MPV positive children requiring ICU care, and 9% did not survive to discharge. Female sex, chronic medical conditions, and hospital acquisition of the virus were associated with mortality. Severe symptoms have also been reported in healthy adults.

Viral coinfection has been described with MPV and is common in young children.¹⁴⁵ Dual infection with RSV and MPV increased the risk of pediatric ICU admission compared with RSV alone in one small study,¹⁹⁸ but this finding was not confirmed by subsequent larger reports.^{127,202,225} Other studies demonstrated no significant clinical differences in children with coinfections, including adenovirus, bocavirus, coronavirus, influenza virus, PIVs, or RSV.^{31,101,105,109,110,128,195,207} The increased sensitivity of molecular viral detection methods has uncovered high rates of codetection for many viruses, not just MPV; the clinical significance of this finding remains unclear.

Streptococcus pneumoniae acute otitis media is associated with MPV infection,^{212,247} and it may be a cause of pneumonia. Verkaik and colleagues²²⁹ noted that frequent carriage of *S. pneumoniae* in children increased seroconversion rates of MPV. Infection with both organisms may contribute to more severe disease.¹⁹⁶ Pneumococcal vaccination decreased the number of children with MPV who have severe pneumonia in both HIV and non-HIV infected children.¹⁴⁰ Secondary bacterial pneumonia following MPV infection has been reported, although the frequency of this complication is unknown.^{6,196} Mice infected with MPV and subsequently challenged with sublethal doses of *S. pneumoniae* exhibited more severe lung disease than did mice infected with MPV or pneumococcus alone.¹²⁰ In vitro models suggest increased adherence of *S. pneumoniae* as a possible mechanism.¹²⁵

Asthma

MPV has been linked to asthma exacerbations, although the incidence is lower than with RSV or human rhinovirus (HRV).^{99,108,176} MPV was detected in 10 of 132 hospitalized Finnish children with acute wheezing.¹⁰⁰ Similarly, MPV was isolated from 7% of adults hospitalized for an acute asthma exacerbation.²⁴² As with RSV, infection with MPV within the first 2 years of life is a risk factor for later development of asthma.⁷³ Broughton and colleagues²⁴ prospectively followed premature infants who developed MPV bronchiolitis within the first year of life and noted that they had decreased lung function at 12 months of age.

Infections in Immunocompromised Persons

Severe and fatal MPV disease has been described in immunocompromised individuals, including solid-organ and stem cell transplant recipients, HIV-infected individuals, chemotherapy recipients, and persons with chronic cardiopulmonary disease. In a study of hospitalized South African children, children with underlying medical problems accounted for 88% of positive MPV specimens, not significantly different from findings with RSV.¹⁵³ MPV is a cause of death in children and adults with hematologic malignant disease,^{34,245} as well as stem cell transplants.^{51,96,199} MPV was detected in bronchoalveolar lavage specimens from 5 of 163 (3%) episodes of acute respiratory infection in stem cell transplant recipients, and 4 patients died.⁶¹ In a retrospective study of hematopoietic stem cell transplant recipients with MPV-positive bronchoalveolar lavage specimens, mortality rates within the first 100 days were 43%, identical to those from RSV.¹⁸¹ Chu and colleagues³⁴ noted that in their cohort of MPV-positive immunocompromised

children, hematopoietic stem cell transplant recipients were more likely to require ICU care compared with patients with other conditions. One patient who tested positive for MPV before transplantation developed symptoms after transplantation and died.²⁸

In a South African study, HIV-positive children with MPV were significantly more likely to receive a diagnosis of pneumonia and experience longer hospitalization, lower mean oxygen saturation, and bacteremia. Children with HIV infection were five-fold more likely to be infected with MPV than were HIV-negative children.¹⁴¹ However, Groome and colleagues⁷⁷ noted that hospitalizations from MPV were increased only in HIV-positive children 5 to 17 years of age, whereas rates in younger children were similar between HIV-infected and HIV-uninfected children. HIV-exposed, uninfected children were more likely to have MPV lower respiratory tract infection than HIV-unexposed, uninfected children.³⁵

MPV causes severe disease in children with underlying cardiac and respiratory disease or prematurity,^{113,153,165,227} with some evidence suggesting that it is more common than RSV in these children, possibly related to the use of palivizumab.²⁵⁷ Esper and colleagues⁶⁶ noted that 34% of patients with MPV had a history of prematurity, chronic lung disease, complex congenital heart disease, or immunodeficiency, findings emphasizing that these children are at risk for MPV disease. Ulloa-Gutierrez and colleagues²¹⁸ described a 3-month-old 27-week premature infant who required 10 days of extracorporeal membrane oxygenation. In a study of preschool children with MPV, 32.7% had a history of severe prematurity (<32 weeks), and they were more likely to have longer hospitalizations, need for supplemental oxygen, and higher severity scores.¹⁶³ Anderson and colleagues⁷ noted that high-risk hospitalized children with MPV were more likely to be more premature and more commonly have chronic lung disease than children with RSV. MPV has been detected in 3% to 12% of adults hospitalized for exacerbations of chronic obstructive pulmonary disease.^{147,185,230}

Encephalitis and Encephalopathy

MPV has been associated with neurologic complications including febrile seizures, status epilepticus, and altered mental status, but there is no conclusive evidence for direct central nervous system infection. Schildgen and colleagues¹⁹² reported a case of one patient who died and had MPV isolated by RT-PCR from brain and lung tissue. Glaser and colleagues⁷⁵ detected MPV by RT-PCR in nasal specimens from four of 1570 patients with encephalitis of unknown etiology. Several other reports described the detection of MPV in a respiratory specimen from patients with encephalitis.^{8,70,84,104,192,228} There are two case reports of detection of MPV RNA in brain or cerebrospinal fluid.^{188,192}

MPV has been isolated from nasopharyngeal specimens in patients with myopericarditis, although the virus has not been directly associated with cardiac disease.^{32,235}

DIFFERENTIAL DIAGNOSIS

Clinical illness caused by MPV cannot be reliably distinguished from disease caused by other common respiratory viruses, including RSV, PIVs, rhinoviruses, and influenza virus. Complications such as acute otitis media and supervening bacterial pneumonia may occur.

DIAGNOSIS

Because detection in tissue culture can require prolonged incubation for viral replication, other diagnostic tests have been used. Shell vial culture offers increased sensitivity over traditional culture.^{126,178} Immunofluorescence assay has demonstrated a sensitivity of 73% and specificity of 97% with RT-PCR as the gold standard.⁵⁷ Direct fluorescent assay has shown similar results.¹⁶⁹ Commercial antibody reagents for immunofluorescent detection of MPV are available. RT-PCR is widely used for detection of the virus in epidemiologic studies; primers have been directed at the F, M, L, P, and N protein.^{17,37,170,220} Real-time RT-PCR directed toward the N gene has a high sensitivity for virus detection and can detect the four subgroups.^{114,142} Several commercial multiplex molecular assays that include MPV are available.^{26,173}

TREATMENT

The mainstay of therapy for MPV infections is supportive care, including oral or intravenous hydration for infants unable to feed, monitoring of respiratory status and oxygen saturation, supplemental oxygen as needed, and mechanical ventilation for respiratory failure. Reports of pharmacologic treatment of MPV are limited to immunocompromised and severely ill patients. Ribavirin, an antiviral agent used in severe RSV infection, has been used in animal models and humans, although there are no controlled studies. Hamelin and colleagues⁸¹ demonstrated that ribavirin reduced inflammation and viral replication in mice with MPV infection. Commercial intravenous immunoglobulin (IVIG), ribavirin, and NMSO₃ effectively inhibited MPV in vitro.^{252,254} Spetch and colleagues²⁰⁹ noted that in a mouse model, NMSO₃ decreased viral replication, weight loss associated with infection, and pulmonary inflammation. Ribavirin, with and without IVIG, has been used in immunocompromised adults.¹⁰⁶ Bonney and colleagues²¹ reported successful treatment of an immunocompromised child with MPV by using intravenous ribavirin and IVIG. Subsequently, oral ribavirin and inhaled ribavirin with and without IVIG have been described as successful in several case reports.^{34,112,200,201} However, ribavirin is not routinely recommended in patients with hematologic malignant diseases or in patients undergoing hematopoietic stem cell transplantation.^{49,90,232} Alternate therapies studied in vitro and in animals include plant-derived compounds and short-interfering RNA.^{43,47,150,174} Human and murine monoclonal antibodies exhibit therapeutic efficacy in animal models, with improvements in viral load and lung pathologic findings.^{80,194,217,241}

PROGNOSIS

Most patients with MPV infection experience a full recovery. Fatalities are uncommon and occur primarily in severely immunocompromised persons (e.g., hematopoietic stem cell or solid-organ transplant recipients, patients receiving intensive chemotherapy, patients with HIV infection), persons with significant underlying conditions (e.g., severe chronic obstructive pulmonary disease), and adults older than 65 years who are in poor health ("frail" older adults). MPV may be associated with the subsequent development of asthma.

PREVENTION

Development of candidate MPV vaccines began shortly after identification of the virus. The F protein is highly immunogenic and is the only target of neutralizing antibodies; in contrast to RSV, the MPV G protein does not induce neutralizing antibodies and is not a protective antigen.^{152,187,205} A recombinant PIV encoding the MPV F protein demonstrated protection against wild-type virus.²¹⁴ Soluble F protein vaccines have shown a reduction in viral titers in cotton rats and hamsters,^{42,87} and addition of the M protein to F subunit vaccines may have an adjuvant effect.² Many of the candidate vaccines produced both homologous and heterologous viral protection.^{87,131,134,204,236} Other candidate vaccines include a Venezuelan equine encephalitis virus–based viral replicon particle vaccine expressing the F protein, which was effective at controlling viral load and producing F-specific antibodies with neutralizing activity in mice, cotton rats, and African green monkeys.^{13,152} Virus-like particles are also a promising vaccine candidate.^{38,131,236} Monoclonal antibodies directed at the fusion protein are effective prophylactically at decreasing viral replication in mouse and cotton rat models.^{36,80,174,194,217} Two different human monoclonal antibodies against the F protein have shown therapeutic efficacy against both MPV and RSV in small animal models.^{36,194} Reverse genetics has been developed for MPV and has been used to develop recombinant strains for vaccine development.^{16,86} Viruses lacking the G, M2-1, M2-2, or SH proteins or with point mutations are attenuated and immunogenic in rodent and primate models.^{14,16,25,88,89,189} A human challenge model has been established, which will facilitate the development and testing of MPV vaccines.²¹³

SUBSECTION VIII Rhabdoviridae

184

Rabies Virus

Charles E. Rupprecht • Stephen J. Scholand

Rabies is an acute, progressive viral infectious disease of the central nervous system (CNS). It causes a devastating encephalitis, classically characterized by hydrophobia, hypersalivation, and certain death. Only warm-blooded vertebrates can be infected, and humans are considered a dead-end host. Sadly, children make up a more than one-half of the total annual deaths around the world.³¹²

The disease occurs following the introduction of virus by a bite or scratch from an infected animal. Rarely, aerosol or mucosal exposure or transplanted tissue enables infection. In most cases, saliva from an infected animal serves as the transfecting medium. Laden with infectious virions, inoculation can occur through breaks in the skin or direct contact with mucous membranes. From there, the virus can attach to and migrate by peripheral nerves to the spinal cord and brain. Encephalomyelitis develops, with subsequent centrifugal dissemination of progeny virions. The clinical symptoms at first may be nonspecific, such as with headache, fever, and malaise. Neurologic symptoms then manifest, such as numbness or paresthesias relative to the inoculation site. Each presentation of human rabies, however, can be quite variable. Inevitably, the disease progresses to coma and almost always death. Recent experience indicates that in extremely rare cases, survival may be possible. The mainstay of medical intervention, however, remains prevention. Redoubled efforts around the world to control this zoonosis have begun, but enormous challenges remain. A thorough appreciation of viral epidemiology, transmission, pathophysiology, and prevention methods is of great value in the study of pediatric infectious diseases.

HISTORY

Rabies is an ancient disease that has plagued humankind throughout history. Frightful myths, admixed with astute observations of the disease, have been described by all major civilizations. For a detailed historical account of rabies throughout the ages, one may refer to a previous version of this chapter and other relevant publications.^{223,264,308} More recently, in this 21st century, rabies remains a major public health problem throughout most of the developing world. Current estimations of the global burden of human rabies suggest that 60,000 or more victims may succumb each year,³¹² with most deaths in Asia and Africa.¹⁶² However, the actual number is unknown as a result of difficulties in reporting and surveillance.²⁷³ Costs in disability-adjusted life years are estimated at more than 3.7 million USD (95% confidence interval, 1.6–10.4 million), with 8.6 billion USD (95% confidence interval, 2.9–21.5 billion) in annual losses.¹¹⁸

Canine rabies is the source for the majority of human cases in the developing world, but it has been eliminated in developed countries. The United States was declared free of canine rabies transmission in 2007,²⁸⁸ and by 2008 most of Western Europe was “rabies free” (except for the disease in bats). However, even with the control of canine rabies in some regions, importation of infected dogs from rabies-endemic countries was responsible for sporadic reintroduction, such as in France and Italy in recent years.^{25,86} Thus, it is important to remain vigilant for rabies reintroduction.⁶³ Whereas the Old World still has canine rabies as an important public health problem, within Latin America, significant progress was achieved, with a 95% decline in human rabies cases since 1983, when a large regional effort for animal rabies elimination was launched.²⁵¹

In the United States, wildlife rabies reservoirs, such as raccoons, skunks, foxes, and bats, remained an important source of rabies at the end of the 20th century. Human and animal rabies prevention recommendations in the United States were adjusted to this reality, and a national oral rabies vaccination program targeted to free-ranging carnivores was launched to contain the spread of wildlife rabies.²⁵⁷ Oral rabies vaccination programs for wildlife have increased in recent times, by using baits containing a vaccinia-rabies recombinant vaccine and, more recently, an adenovirus-rabies recombinant vaccine.⁹¹ Although progress in the development of tools to control carnivore rabies was notable in the beginning of the 21st century, little progress has occurred regarding rabies transmitted by bats. This is because of an extensive global biodiversity of bats, and as such, these mammals and the rabies viruses circulating within those populations represent a new frontier for rabies management.^{17,71,218}

Besides basic approaches focused on animals, advancement of human rabies biologics was also notable in the late 20th century. Both human rabies immune globulin (RIG) and rabies cell culture vaccines, to replace older nerve tissue vaccines (NTVs), were made available.^{28,311} These more modern rabies biologics became the standard in many developing countries.^{31,241} Historical NTVs are not recommended by health authorities and are in the process of being phased out worldwide. A few remaining countries in Africa and Asia, however, still permit their use.⁵⁶ Social determinants underlying basic health disparities, such as poverty, limited education, and geographic isolation, became relevant factors for more innovative strategies to control and prevent rabies at the local community level.²⁵⁰ A global strategy for a transdisciplinary response to rabies is required, given increased movements of disenfranchised populations, illegal hunting and trade of animals, and overnight travel. In this regard, new stakeholders and partners were created in the 21st

century.²¹¹ These global academic, industrial, and nongovernmental organizations (NGOs) coordinate efforts for advocacy, education, awareness, and joint human and animal campaigns for improved disease prevention and control in the world. Coordinated efforts with leading rabies research groups, international philanthropic institutions, and global health agencies, such as the United Nations Food and Agriculture Organization, World Organization for Animal Health, Pan American Health Organization, World Health Organization (WHO), and many others have had a major impact.¹⁷⁹ For example, the first global rabies campaign was held in 2007, by recognizing World Rabies Day, and September 28 was established officially as a date for rabies outreach. Currently, more than 150 countries participate annually in World Rabies Day activities. Another important underlying element for global rabies mitigation in the 21st century was the adoption of a One Health approach, fostering collaborative work among animal, environmental, and human health sectors to accomplish management of zoonotic diseases. Such a basic strategy is a current mainframe for integrated public health actions, especially concentrated on diseases of nature.¹⁵⁴

ETIOLOGY

As fundamental hosts, all mammals are believed to be susceptible to infection with the viruses that cause rabies. In fact, rabies virus proper (RABV) is only one of several related viruses that cause the disease.

The gross morphologic characteristics and biochemical composition of the etiologic agents of rabies place them within the family *Rhabdoviridae*, genus *Lyssavirus*. These viruses, however, share antigenic and genetic relationships that set them apart from other rhabdoviruses.

They can be distinguished by fluorescent antibody and complement-fixation tests, reactions with monoclonal antibodies, and, importantly, sequencing studies.

The *Lyssavirus* genus contains at least 14 viruses recognized by the International Committee for the Taxonomy of Viruses (ICTV), and all of them cause rabies. The 14 species include RABV as the type species, Aravan virus, Australian bat lyssavirus (ABLV), Bokeloh bat virus, Duvenhage virus (DUV), European bat lyssavirus (EBLV, types 1 and 2), Ikoma virus (IKOV), Irkut virus (IRKV), Khujand virus, Lagos bat virus (LBV), Mokola virus (MOKV), Shimoni bat virus (SHBV), and West Caucasian bat virus (WCBV).^{39,148,169,170,188,242} Fig. 184.1 shows the known lyssaviruses and the three phylogenetic groups in which they are classified.¹⁷ The lyssaviruses are antigenically variable, with IKOV, LBV, MOKV, SHBV, and WCBV being the most distant from RABV.¹³⁶ Additionally, many more lyssaviruses will be discovered in the near future as scientists conduct pathogen discovery, especially in poorly studied animal populations. Besides RABV, cases of human disease have been described with ABLV,¹⁰¹ DUV,²⁸⁶ EBLV,¹⁰⁰ IRKV²⁹ and MOKV lyssaviruses.⁸⁷

Electron microscopic studies reveal that these viruses are rod or bullet shaped. Viruses typically mature at cytoplasmic plasma membranes and intracellular membranes of the endoplasmic reticulum in infected cultured cells (Fig. 184.2).¹³⁷ Standard virions are approximately 75 nm in diameter and 160 to 180 nm in length. Regular arrays of standard-size virions maturing from plasma membranes are observed in infected salivary glands. Budding of virus from plasma membranes is much less pronounced in neurons of the CNS than in cell culture or salivary gland cells. However, meticulous electron microscopic examination of

FIG. 184.1 Phylogenetic analysis of characterized *Lyssavirus* isolates based on 405 nucleotides of the nucleoprotein, grouped by phylogenetic groups I, II, and III and indicating main hosts and reservoirs identified. ABLV, Australian bat lyssavirus; ARAV, Aravan virus; DUVV, Duvenhage virus; EBLV, European bat lyssavirus; IRKV, Irkut virus; KHUV, Khujand virus; LBV, Lagos bat virus; MOKV, Mokola virus; RABV, rabies virus; SHBV, Shimoni bat virus; WCBV, West Caucasian bat virus. FIG. 184.2 Structural diagram of a *Lyssavirus*. (From Orciari LA, Rupprecht CE. Rabies. In Versalovic J, Carroll KC, Funke G, et al, editors. *Manual of clinical microbiology*, 10th ed. Washington, DC: ASM Press; 2011:1470–1478.)

experimentally and naturally infected tissues has revealed that budding from membranes of perikarya and dendrites, as well as the presence of virus in intracellular spaces of brain (especially at synaptic junctions), occurs regularly.¹³⁹ In addition, CNS neurons often exhibit both typical and bizarre morphologic forms of virus maturing in the cytoplasm. Cytoplasmic forms often develop in proximity to nucleocapsid matrix inclusions forming the classic Negri bodies.¹⁹⁰

The basic *Lyssavirus* virion consists of a molecular composition somewhat similar to that of the other rhabdoviruses, such as vesicular stomatitis virus. The virion comprises a helical nucleocapsid core, which contains a single-stranded RNA genome coupled to a nucleoprotein, a phosphoprotein, and a large protein representing an RNA-dependent polymerase.⁶⁰ This core is surrounded by a lipoprotein membrane, which contains a matrix protein, an external glycoprotein embedded in the envelope, and several lipids (primarily phospholipids and cholesterol).^{27,261} The genome is a single-stranded RNA molecule containing approximately 11,932 nucleotides with a molecular mass of approximately 4.0×10^6 Da.²³ The genome is negative stranded; that is, it must be transcribed to produce messenger RNA necessary for replication. Defective virions containing characteristic (for a given strain) sizes of incomplete RNA molecules have been demonstrated in cell culture–propagated virus populations, but their occurrence or role in natural infections has not been determined.

Important surface antigenic properties for these viruses are associated primarily with the glycoprotein,²⁶¹ a polypeptide containing three major oligosaccharide side chains.⁷² The glycoprotein is the sole antigen responsible for induction of and reaction with virus-neutralizing antibodies. Antibodies to the nucleoprotein administered passively have no virus-neutralizing or protective capacity. Nucleoprotein antibodies are essential, however, for the diagnostic detection of intracellular viral antigens in the CNS by immunofluorescent staining.³¹⁴ Active immunization with rabies nucleocapsid may contribute to immune protection, especially to heterotropic lyssaviruses, apparently by induction of a *Lyssavirus*-specific T-cell immune response, but further work is needed to appreciate the role of other viral antigens for prophylaxis.^{40,78}

Historically, viral specificity can be recognized on the basis of genomic sequence analysis²⁸⁰ and differentiation by monoclonal antibodies. By these means, animal-specific variants and geographic distribution of viruses can be discerned, and isolates from human cases can be traced to the animal and place of origin.²⁶⁰ Researchers have suggested that lyssaviruses, like several other RNA virus populations, may exist as a quasispecies. The presence of such viral subpopulations may permit rapid adaptation to new hosts.^{160,202}

Antigenic differences between both strains of classic laboratory-fixed virus strains and variants of different field isolates of diverse origin

have been detected with the use of monoclonal antibodies³¹⁶ directed against viral antigens, including the glycoprotein and nucleoprotein.⁷⁷ The use of monoclonal antibodies allowed rapid distinction of RABV from the other rabies-related lyssaviruses.²³⁸ Studies with monoclonal antibodies have revealed that, worldwide, clustering of certain RABV antigenic subtypes is geographic and may be species specific.²²⁵ Many genetic groups of RABV with relatively specific geographic localizations exist.^{32,260} Within those areas, the viruses may be transmitted by different species, such as dogs or foxes. In the United States, readily distinguishable subtypes of RABV have been determined to circulate in each of the major mammalian reservoir species (primarily skunks and raccoons) and in bats.²⁶ In all well-studied rabies enzootic areas, researchers have determined that rabies circulates predominantly in a limited number of mammalian species characteristic of that area, and a major antigenic phenotype is characteristic of that transmission cycle.⁷⁷ However, distinct bat-adapted RABV may circulate independently in these areas or in areas where other animals (e.g., dogs) are free of rabies. Different geographic subtypes of RABV share varying proportions of the immunologically important glycoprotein epitopes with the vaccine strains of virus. Those RABV subtypes isolated from human cases in the United States have been shown to differ from vaccine strain viruses in their antigenic composition.³¹⁶ Despite intense investigation, however, no evidence supports the contention that cross protection between the RABV vaccine and antigenically distinguishable wild-type viruses is reduced to a degree justifying inclusion of new RABV strains in human vaccines. Physicians should have every reason to believe that present vaccines protect against all classic RABV and other members of the phylogenetic group I, provided the vaccine is sufficiently potent. The same degree of cross reactivity does not exist for the other lyssaviruses in phylogenetic groups II and III. Studies using virtual tridimensional models demonstrated that antigenic distances among the known lyssaviruses are the basis for antigenic variation and unequal response to rabies biologics.¹³⁶

All lyssaviruses have been suspected or associated with bat reservoirs, except MOKV.²⁴⁵ The DUV, IKOV, LBV, MOKV, and SHIBV lyssaviruses were identified only in Africa; the WCBV was isolated in Eurasia only.^{84,299} Many variants of RABV exist, and such variants are adaptations to diverse mammalian reservoirs and may be specific to certain geographic regions. For example, RABV in bats is widely distributed in the New World, and viral variants specific to different bat species exist in North America, as well as to vampire bats in Latin America, and to insectivorous and frugivorous bats recognized in South America, such as in Chile and Brazil.^{26,102,221,242,252}

With regard to public health, animal rabies reports include laboratory confirmation in most of the mammal species in contact with humans, with an obvious surveillance bias.²⁴² Laboratory isolation and propagation of virus may be accomplished readily in mice or other standard laboratory animals; in vitro in neuroblastoma or certain hamster cell cultures; or, after adaptation, in certain cell lines of human or other mammalian origin.²¹⁵

TRANSMISSION AND EPIDEMIOLOGY

The main mode of rabies transmission is through inoculation of the virus by an animal bite. Once an injury to the skin occurs, infectious saliva may contaminate the wound. Thus, the virus may gain access to nerves as well as muscle tissue. Unlike skin, mucous membranes (e.g., of the eyes, nose) have no protective epithelial barrier and therefore serve as other potential entry points for the virus, such as a splash exposure of saliva to the mouth. A rabid animal's saliva contains virus capable of initiating productive infections. Importantly, however, viral shedding in the saliva can occur for several days before the classic clinical signs occur in most animals.^{93,204} This makes capture and observation of the biting domestic animal very important; otherwise, a default pathway assuming an RABV exposure typically ensues. Animal scratches may become contaminated with saliva during an exposure and therefore are managed in the same way as bites.⁷⁹

Other secretions from rabid animals, such as urine, feces, and milk, are considered at low or no risk for viral transmission⁴³; however, exposure to those secretions can potentially allow transmission of other diseases.¹⁸⁷

Consuming the meat of rabid animals is not recommended; however, in the developing world, rabid animals, especially livestock, may be killed and eaten, even animals with the onset of neurologic signs. Although eating cooked meat of a rabid animal is not considered a risk for viral transmission, the people handling the carcasses and in contact with the head, saliva, brains, nervous tissues, and other organs may be exposed.²⁹³

In very rare circumstances under special conditions, infection may occur by inhalation of virus. Experimental studies with animals left exposed in caves heavily colonized with bats indicate that this form of transmission is possible.⁶⁶ In contrast, bat “fly by” exposures are not considered exposures to rabies. Concentrated virus aerosols produced in the laboratory setting have caused human rabies cases.¹⁴⁹ Optimum biosafety practices and equipment will prevent this kind of exposure. Finally, transmission of rabies has occurred from human to human by corneal and other tissue transplants.^{46,137,186,263,291} Because human rabies in the United States and Europe is very rare, occasionally a case will be missed, and screening may neglect the possibility of death from rabies. There are a number of well-known rabies cases transmitted by corneal transplant from fatal cases of undiagnosed encephalitis.^{137,263} Several other human rabies cases caused by organs transplanted from donors with unrecognized rabies encephalitis have also occurred, thus raising concerns about proper diagnostics available for viral encephalitis in the modern health care setting.^{186,263,291}

Domestic animals constitute the largest sources of human exposure in most parts of the world. Dogs are the primary reservoirs and vectors in Asian countries, such as India, Indonesia, China, and the Philippines. Cats are a distant second in terms of RABV transmission. The magnitude of the rabies problem is illustrated by the observation that approximately 12,000 to 20,000 deaths are attributed to rabies annually in India alone,³¹⁰ and as many as 50,000 to 100,000 deaths occur each year throughout the world.¹⁶² The incidence of rabies deaths in India of 2 to 4 in 100,000 population may be exceeded only by that of Ethiopia, where the rate may approximate 18 in 100,000.¹²² The total number of people given postexposure prophylaxis (PEP) is estimated to exceed 12 million or more annually. In contrast, many areas, including Japan, Singapore, many parts of the Caribbean, New Zealand, Pacific Oceania, and others, are considered “rabies free.”^{16,30} China has averaged about 1500 human cases per year, but in at least 1 year there were more than 3000 cases. Dogs were by far the most important sources of human rabies.²⁶²

The veterinary challenge has always been to vaccinate the local dog population adequately, a measure that would essentially resolve the majority of the problem in these developing countries. Given the severely constrained resources in some areas and the lack of adequate infrastructure, a cycle of neglect continues.

Indeed, the burden to people is directly related to the perpetuation of the disease in local animal populations. For example, in a single year of an urban epizootic of dog rabies in one city in Mexico, an estimated 2.5% of the human population received dog bites, and 2.7% were given rabies PEP.⁸⁵ In Africa, the dog still is the most important reservoir and vector, although in the southern portion of the continent, jackals and mongooses also are common sources of viral exposures.^{22,62,155,331,332} In much of Africa, the incidence of rabies in humans and dogs has increased in recent years because of social and political disruptions.^{310,311} Hence, rabies is a significant tropical disease. Resources directed toward vaccinating dogs against rabies would follow a One Health paradigm and yield great dividends to animals and humans alike.²¹¹

Rabies in Central and South America is related predominantly to dogs, but vampire bats also have considerable importance.¹⁴⁷ Although humans sometimes are bitten, they are also exposed to rabid cattle infected by these bats. Fortunately, despite these relatively common exposures, viral transmission from livestock to humans is an extremely rare event.⁶⁹

In the United States and Canada, foxes and skunks once were the primary rabid wild animals that most commonly attacked humans. In more recent years, the raccoon has replaced these carnivores as the most important potential source of infection. The reason is because of an outbreak of rabies in these animals stemming from the introduction of infected animals into the mid-Atlantic states from Florida and southeastern Georgia. Subsequently, a rapid expansion of raccoon rabies

moved northward and southward in North America, in a range now continuous from Canada to Florida and west to Ohio.^{44,80} This massive spread of raccoon rabies continues to incur large costs in human prevention related to PEP, domestic animal care, and efforts at wildlife control. Fortunately, human cases of rabies attributable to raccoons have remained very rare.^{35,45,200,291}

The significance of bats to rabies epidemiology varies globally. In the United States, bats serve as a reservoir in every state except Hawaii. Bats are responsible for a high proportion of all North American cases, including those in persons with no antecedent history of animal bite.²⁴ For example, between 2003 and 2015, an average of three human rabies cases occurred per year,²⁰⁰ of which almost three-fourths were bat RABV variants, discounting imported and transplant cases. A review from 1990 to 2005 showed that more than 90% of domestic cases (42 of 45 cases, excluding four transplant-transmitted infections)²⁶³ were caused by bat RABV, predominantly from the silver-haired (*Lasionycteris noctivagans*) and eastern tricolored bats (*Perimyotis subflavus*).^{24,90,187}

Viruses isolated from silver-haired bats may be better able to grow in non-neuronal cells, and although prophylactic vaccination is effective when exposure is recognized, the infectiousness of these viruses apparently appears high.²⁰² In Colorado, 15% of laboratory-tested bats were found rabid.²¹⁵ The most recent national data from the Centers for Disease Control and Prevention (CDC) indicate that approximately 6% of submitted bats were rabid from biased surveillance of ill animals and those in contact with humans.²⁰⁰ As with other animals, clinical signs may not be apparent immediately, even though the animal is infected.²³¹ However, certain behaviors raise suspicion, and bats found paralyzed on the ground have a high likelihood of being rabid, compared with healthy, wild-caught individuals, in which the prevalence is typically much less than a fraction of 1%.⁶⁵ Problems regarding human exposure to bats that are potentially rabid may arise. In particular, a child sleeping in a room may not be able to report a scratch or a bite, and there may be little physical evidence of such an exposure.^{166,297} Ideally, capture of the bat with laboratory analysis of the brain would help guide therapeutic decisions. Vaccination may be indicated if the bat is confirmed to be rabid. Finally, decisions may favor vaccination if a bat entered a room but escaped, and there is a reasonable probability of bite exposure. In Europe, bats have been responsible for transmission of other rabies-related lyssaviruses.¹⁰⁰ Despite the rarity of such an event, bats and vampirism were linked inextricably in legend with Dracula, the 15th-century despot who lived in current-day Romania.¹²⁴ In contrast, true vampire bats (subfamily Desmodontinae) in Central and South America are responsible for considerable losses of domestic animals and for human rabies cases.^{147,178}

On average, about two to three cases of human rabies are reported in the United States each year, but thousands of animals are diagnosed as rabid by laboratory analysis. All reservoirs are within wildlife hosts, with spillover infection to other mammals. The distribution of infection among animals is shown in Table 184.1.^{24,200} The cat continues to be a more important host of domestic rabies than the dog in the United States. In Puerto Rico, the mongoose is the major reservoir, and almost all the mongooses that bite people may be expected to be rabid.²⁰⁹

True canine RABV transmission has been eliminated in the United States. The most recent data from the CDC reports that only 59 dogs were found rabid in 2014, in contrast to the thousands of rabid dogs during the 1940s. True vaccine failure is rare. Of those rabid dogs for which immunization records were available, none had been immunized or had proper immunization.²⁰⁰ Interestingly, the RABV variants found in dogs were largely from skunk variants ($n = 17$), with raccoon rabies second ($n = 7$); however, the majority of rabies variants were not typed ($n = 33$). Thus, public health authorities advocate RABV variant testing for all dogs as surveillance against reintroduction of canine rabies by imported dogs.

Vaccination has reduced the overall prevalence of rabies in cats in the United States, yet these animals remain the most common rabid domestic animal, comprising almost two-thirds of the total.²⁰⁰ Although only about one-fourth of the rabid cats had RABV variant typing, data showed that primarily skunk (59%) and raccoon variants (40%) were implicated. Clearly, more public health emphasis on immunizing cats is needed.

From Monroe BP, Yager P, Blanton J, et al. Rabies surveillance in the United States during 2014. *J Am Vet Med Assoc.* 2016;248(7):777–788.

Wildlife rabies continues to be a major concern, with more than 6000 rabies-positive animals reported during 2014. Most rabid animals were raccoons (30%), bats (29%), and skunks (26%). Table 184.1 summarizes the data for wildlife in more detail.

Rabies host shifts were recognized during the last decade for multiple species. Virologists refer to this as spillover, as a virus from one primary reservoir that may transmit to other species of animals. This transmission could be a dead end (as in humans) or may allow for adaptation, differentiation, and circulation of the virus in a new reservoir. Thus, a host shift could occur, as described in Arizona where rabies virus jumped species from bats to foxes and skunks.¹⁷¹ This important phenomenon highlights the potential dangers of uncontrolled wildlife rabies and supports the need for continued surveillance and research. For example, there could be significant public health and veterinary impacts should a new rabies outbreak occur.

PATHOGENESIS

The initial stages of RABV and other lyssavirus infection are perhaps the least understood. Disease certainly depends on the entry of the virus into peripheral nerves, after which centripetal spread occurs rapidly toward the CNS. Replication of virus in muscle cells at a peripheral inoculation site has been demonstrated experimentally, and the virus has been suggested to persist in myocytes for many days after inoculation,⁵² but this has not been proven to occur in nonexperimental situations.^{53,207} Nonetheless, replication at a low level in myocytes, followed by subsequent infection of nerve cells, would help to explain the occasionally extended incubation periods of disease. Entry of virus into the peripheral nerve endings is mediated by attachment to various receptors, such as the nicotinic acetylcholine receptor (nAChR) and other ganglioside receptors, such as neural cell adhesion molecule (NCAM or CD56).^{172,253} Once the virus is in nervous tissue, spread can occur by cell-to-cell contact.^{51,281} In any case, virus is thought to enter peripheral nerves at an extremely variable time after exposure, presumably at the site of neuromuscular or neurotendinal spindles, at motor end plates, or (in the case of aerosol exposure) at olfactory end organs.²⁰⁸ Viremia is of no known importance in the dissemination of infection.

Historically, amputation or cauterization of the bite site was used as a means of intervention even before pathobiologic insights. More

recently, the finding that virus transits along nervous pathways has been demonstrated directly by repeated experimental observations, such that the progress of infection may be interrupted by surgical excision or chemical destruction of nerves at sites distal to the inoculation site.¹² Central progression of virus along neuronal pathways has been demonstrated by electron microscopic, immunofluorescent, and serial infectivity studies. Virus appears to be sequestered within neuronal cells during transmission (by axoplasmic flow) through peripheral nerves, and the virus can therefore be used experimentally to trace synaptic circuits.¹⁵⁶ Intra-axonal retrograde transport appears to be aided by interaction of the viral phosphoprotein (P protein) with the cytoplasmic protein dynein light chains.^{143,230} Minimal numbers of virions are observed within neurons, and connective tissue elements of nerve sheaths are not involved. Given viral tropic stealth, little maturation or release of virus from nerve plasma membranes occurs during transit, and scant or no virus is presented to the immune system. This feature explains in part the absence of detectable humoral antibody until late in the disease that is characteristic of even prolonged incubation periods with rabies. Nonetheless, neutralizing antibody may enter the neuronal cytosol by endocytosis and block viral transcription.⁷⁶ One study described an immunoevasive strategy triggered by RABV to infect the CNS. Moreover, LGP2, a protein that regulates retinoic acid-inducible gene I (RIG-I), mediates immune responses and reacts with negative immune signals in the presence of negative-stranded RNA viruses, thereby preventing the elimination of T cells infiltrated by virus.⁵⁵

Entry from the periphery to brain occurs through the spinal cord or cranial nerves. Early selective infection of the limbic system in the brain may cause disease characterized by extreme excitability and agitation (furious rabies), whereas the encephalitic depressive symptoms are associated with early, widespread infection in the brain.¹⁹⁸ In either case, infection rapidly spreads to affect nearly all brain neurons within a few days of the onset of brain entry and acute CNS symptoms. Brain infection leads rapidly to death by respiratory or cardiac failure. Fatal cases of encephalitis reveal little damage of neuronal cells, despite the ubiquitous neuronal infection.¹⁰⁴ Alternatively, persons kept alive by vigorous supportive therapy for lengthy periods after onset of disease may develop severe histopathologic encephalitic lesions. Studies in mice have shown that apoptotic mechanisms may be induced by laboratory strains of RABV,^{141,284} but other virulent street RABV variants induce little if any apoptosis by expressing less G protein in neurons.²⁰³ RABV G protein expression may contribute to pathogenesis by downregulating apoptosis.²⁰³ Although ascending infection is specific to neurons, once the CNS is infected, virus spreads centrifugally to peripheral nerve plexuses, the salivary glands, muscle fibers, hair follicles, and other innervated sites.¹⁴²

The entire manner of progression of the infecting virus, particularly those points in its transit vulnerable to immune intervention, remains to be fully determined. Clearly, preexisting humoral antibody protects by inactivating virus before it gains entry into the nervous system. After an RABV-naïve person is exposed to RABV, disease can be delayed or prevented by passive antibody, interferon (IFN) treatment, or both,¹⁴⁶ but protection becomes efficient only when active immunization with potent vaccine accompanies such PEP.

The presence of neutralizing antibodies after exposure but before illness is a key facet of protection against rabies. However, studies have demonstrated the complexity of the immune response after infection.^{103,210} Although some experimental evidence argues for the importance of cytotoxic T lymphocytes in protection against rabies, Hooper and colleagues¹³⁴ infected mice that were unable to mount a cellular response and found no difference in disease with respect to normal mice. Nonetheless, early inflammatory responses, as well as rapid production of antibody, correlated with recovery from rabies. Thus, IFN and other mediators may supplement antibody in the prevention of disease. Interestingly, virus-specific cytotoxic T lymphocytes do not usually develop during infection, and street RABV may act as an immunosuppressor. Moreover, chemical immunosuppression enhances the development of experimental rabies. IFN¹³ and interleukin-2,²¹³ both important immunomodulators produced by cells, enhance protection against rabies. More sophisticated understanding of rabies pathogenesis is required before ideal combinations of immunotherapeutic procedures, possibly including IFN, can be applied.

The reverse side of the infection-immunity coin is reflected by the “early death” phenomenon, in which exposed animals or humans develop earlier onset of rabies if previously they received incomplete immunization. Sugamata and associates²⁶⁷ demonstrated that early death depends on the presence of T cells, a finding indicating that it is mediated by an immunopathologic cellular response. In addition, some investigators have argued that cytotoxic T lymphocytes actually may contribute to rabies neuritic paralysis.^{267,309}

CLINICAL MANIFESTATIONS

Animal Rabies

Rabies encephalitis in animals is expressed as either a paralytic (dumb) or encephalitic (furious) syndrome. Typical infections are characterized by behavioral changes and a rapid clinical course leading to paralysis, coma, and death. Rarely encephalitis can be nonfatal, and the animal recovers.¹⁰ Because literally millions of animal bites of humans occur annually in the United States, the identification of aberrant behavior and whether animal attacks can be considered provoked or unprovoked are critical factors in many decisions to administer prophylaxis against rabies.¹¹³

The prodromal stage of disease is marked by nonspecific signs, such as restlessness and malaise. Subsequently, placid dogs, cats, cattle, or horses may become vicious. Wild animals may lose their fear of humans and of periurban areas. Thus, rabid foxes, normally nocturnal, may be seen wandering aimlessly in the daylight. Similarly, rabid bats often have been encountered flying oddly in daytime hours. Early behavioral changes are not accompanied by paralysis.

The clinical course progresses rapidly to either dumb or furious disease. Dumb rabies typically is a depressed ascending neurologic type disease. In addition to lethargy, selectively severe paralysis of throat muscles may be observed, which causes drooling of saliva because of difficulty in swallowing. Hydrophobia is not noted in animals. Furious rabies is characterized by an unusual state of alertness in which any visual or sound stimulation may incite an attack. Animals may roam, indiscriminately biting at inanimate objects. Caged animals have been observed biting furiously at traps without obvious pain. Companion animals, such as dogs and cats, may exhibit unusually affectionate and playful behavior and then suddenly bite those playing with them. Very aggressive biting behavior may occur in herbivores such as horses, mules, and cattle, which may produce outright fatal injuries.

Both dumb rabies and furious rabies have a rapid clinical course in domestic and wild animals. The period between onset of prodromal signs and death caused by respiratory paralysis rarely exceeds 7 to 10 days.²⁷⁴ Although 10 days usually is given as the limit of virus excretion in the saliva of dogs before death supervenes, rare exceptions involving longer excretion have been reported experimentally and in animals observed in both Africa and Asia.^{92,287}

The diagnosis of rabies in an animal depends on the demonstration of postmortem viral antigens in the brain by fluorescent antibody tests or of viral RNA by reverse transcriptase polymerase chain reaction (RT-PCR) followed by sequencing.

Management of Animal Rabies

Aside from the historical ineffective large-scale removal of potentially rabid animal species, such as community dogs, most modern control methods focus on the induction of herd immunity by vaccination. In domestic animals, immunization is accomplished readily by a variety of veterinary vaccines, although boosters must be given annually or after other stated intervals, depending on the product.³⁵

In wild animals, primarily raccoons in the United States and foxes in Europe, oral vaccination with baits containing recombinant-vectored RABV glycoprotein or attenuated live virus has been successful,^{80,217} with the more recent addition of a rabies-adenovirus recombinant vaccine.^{133,257,279}

Human Rabies

The incubation period in human rabies has been observed to be quite variable. Most cases develop within 3 weeks to 3 months following an exposure (20–90 days). About 14% of cases occurred after 1 year in a

large case series of patients with rabies.⁷⁹ Some well-documented cases have occurred as long as 6 to 8 years after the bite.^{26,296} The longer incubation times, reputed even up to 27 years, may result from unrecognized exposures.⁷⁹ In contrast, the shortest incubation periods reported range from 4 to 7 days. These cases may occur with direct viral inoculation into the brain, such as a dog bite puncturing a child's skull.

Incubation periods are longer after bites on the legs than after bites on the face. The reason for this appears to be related not to the length of the nerve that the virus must traverse, because it travels rapidly even from the farthest site, but to the extent of innervation of different parts of the body. Bites on the tips of the fingers or on the genitalia have relatively short incubation periods for this reason. Children in general tend to have shorter incubation periods than adults.

Hemachudha¹²⁶ published a comprehensive review of human rabies. The first symptoms of rabies usually are vague and insidious. The patient simply may feel unwell or have anxiety or depression. Some fever or nausea may be present. A striking prodromal symptom is itching, pain, or tingling at the site of the bite. This paresthesia is not present always and may take various forms, but its localization is a definite harbinger of rabies. The prodrome lasts 2 to 10 days, when the acute neurologic phase begins. The symptoms of this second phase are divided into furious versus paralytic rabies, with most cases being in the furious category. The signs and symptoms as reported from human rabies cases in the literature over the last 50 years (1958–2011) are listed in Table 184.2.

In furious rabies, the emphasis is on agitation, hyperactivity, fluctuating consciousness, bizarre behavior, and perhaps nuchal rigidity. Sore throat and hypersalivation are prominent complaints, and laryngospasm may cause hoarseness. A high percentage of human cases exhibit hydrophobia.²²⁴ In fact, in many clinical settings where advanced diagnostics are lacking, the presence of a dog bite history and the sign of hydrophobia are considered sufficient to make the diagnosis.³¹² The disease of rabies itself, in older literature, was sometimes referred to as “hydrophobe.” Such a dramatic presentation is a startling sign and is considered pathognomonic of furious rabies. Initial attempts to swallow liquid result in painful spasms of the pharyngeal and laryngeal muscles, with aspiration into the trachea. A conditioned response appears to be created, in which fear exacerbates the actual spasms. Warrell and associates³⁰² hypothesized that brainstem encephalitis leads to destruction of inhibitors of inspiratory motor neurons. Respiratory tract instant reflexes are exaggerated, leading to inspiratory spasms. Hydrophobia has an important psychological element. At times, the sound of rushing water or the sight of water can induce the terrible reaction.³⁰⁵ Interestingly, hydrophobia has been reported in only about one-third of the human cases in the United States,²²⁰ and with even less frequency among children affected with a vampire bat rabies variant (Table 184.3). Whether this may have to do with the infecting virus variant (bat vs. dog rabies)²⁸⁵ or clinical familiarity with rabies remains unknown. Also frequently present is aerophobia, in which spasms occur when a current of air is fanned across the face. Priapism, spontaneous ejaculation, and increased libido also have been reported.

The neurologic examination findings in rabies are not uniform. In fact, virtually any neurologic finding can occur. Meningismus is somewhat common. Cranial nerve abnormalities can be seen, especially paralysis of the palate and vocal cords. Deep tendon reflexes may vary from hyperactive to absent, and involuntary movements are prominent.^{79,285,305} Table 184.2 also examines clinical differences in dog-associated versus bat-associated cases. Patients with dog-acquired cases tended to have greater incidence of hydrophobia, aerophobia, and encephalopathy. Patients with bat-acquired cases, in contrast, exhibited more cranial nerve abnormalities and motor and sensory symptoms. These data certainly have limitations related to the heterogeneity of reporting, including the lack of detailed assessments and nonstandardization. These differences could, however, relate to viral pathogenicity, viral tropism, route of inoculation, or other factors that are worthy of further study.²⁸⁵

A distinct pattern of neurologic involvement is shown by approximately 20% to 30% of patients with rabies, particularly those bitten by vampire bats. Flaccid paralysis may start in the limb that was bitten originally and spread to other limbs. The cranial nerves become involved, and the face, rather than showing agitation, becomes expressionless.

TABLE 184.2 Select Clinical Aspects of Human Rabies: Dog vs. Bat Cases, A Review From the Published Literature, 1958–2011^a

Clinical Feature Rabies Specific	Naturally Acquired N (%)	Dog Acquired N (%)	Bat Acquired N (%)	Dog vs. Bat Difference

^aLack of uniform reporting accounted for variance in each characteristic. A positive difference in dog to bat comparisons indicated a higher percentage of cases favored dog-transmitted rabies, whereas a negative value favored bat cases. Naturally acquired cases were those acquired (or presumed acquired) from an animal vector, whereas transplant cases were excluded. Modified from Udow SJ, Marrie RA, Jackson AC. Clinical features of dog- and bat-acquired rabies in humans. *Clin Infect Dis*. 2013;57(5):689–696.

Hydrophobia is not a common feature. Paralytic rabies is confused easily with Guillain-Barré syndrome. Hemachudha and colleagues^{130,132} emphasized the importance of fever, intact sensation, urinary incontinence, and percussion myoedema in paralytic rabies.

The cerebrospinal fluid (CSF) is abnormal in a minority of patients, particularly those with clinical meningitis. When abnormal, the CSF shows mild pleocytosis, mainly mononuclear. The peripheral white blood cell count shows increased polymorphonuclear cells.

Magnetic resonance imaging shows involvement of gray matter in the hippocampus, hypothalamus, and brainstem.^{128,189} Advanced magnetic resonance imaging techniques such as diffusion-weighted imaging and diffusion tensor imaging can provide finer imaging about microstructural and macrostructural damage from rabies encephalitis.¹⁷⁷ Brain imaging is, of course, only adjunctive because findings maybe absent or otherwise nonspecific.

The acute neurologic phase lasts 2 to 10 days, with eventual deterioration of the patient's mental status into coma. The patient may survive in this state for 2 weeks or more, particularly in dumb rabies. Before the final deterioration, the patient may have alternating periods of wild agitation and alert cooperation. During the alert state, patients may be able to discuss their illnesses and express fear of impending death. However, most often, death rapidly follows onset of coma unless intubation and ventilatory assistance are offered, in which case survival may be prolonged for weeks to even months. During the comatose state, a

variety of problems may manifest, including cerebral edema, inappropriate antidiuretic hormone secretion, diabetes insipidus, and other manifestations of hypothalamic dysfunction; hypotension or arrhythmia; and pneumonia. Death caused by rabies in the acute stage occurs because of cardiac or respiratory problems. Cardiac arrhythmias with circulatory collapse commonly occur, and virus may be recovered at autopsy from cardiac tissue that shows pathologic evidence of myocarditis. Respiration becomes increasingly labored, and death may occur during a laryngeal spasm or from aspiration.

However, cases of spontaneous recovery and survival have been documented, thus challenging conventional opinion of absolute rabies mortality.^{1,48,49} Additionally, published evidence of survival after bites from rabid vampire bats without clinical rabies among indigenous Amazon communities challenges the paradigm of certain fatality from viral exposures.¹⁰⁹ Survival also has been documented in a small number of individuals who had been vaccinated,^{2,41,121,227} as well as in an unvaccinated 15-year-old girl who was treated with coma induction, midazolam, ribavirin, ketamine, and amantadine.³²⁵ The last two drugs may have rabies receptor-blocking ability. This experimental rabies treatment has been termed the Milwaukee Protocol, and its original version has been modified by dropping ribavirin because of its effect delaying immune response, adding tetrahydrobiopterin to cover the deficiency observed in CSF, and including calcium channel blockers to prevent vasospasm.³²³ Using the Milwaukee Protocol, a 15-year-old boy survived

rabies in Recife, Brazil, but this patient received rabies vaccine and developed the disease anyway.²¹⁴ Additional attempts for the use of the Milwaukee Protocol were not successful for survival but resulted in extended survival, thus allowing an increased understanding of the complex pathophysiology of rabies, its complications, and viral clearance.^{8,138,234,324} Many failures of the Milwaukee Protocol have been recorded, and the requirement for a high level of intensive care and laboratory handling of cases may not be possible to fulfill in small hospitals or health care systems with limited budgets, such as in the developing world, where the greatest impact can be achieved with rabies prevention activities.¹⁴⁰

DIAGNOSIS

The diagnosis of rabies in humans begins with its discovery in the implicated animal. Hopefully, the animal remains available for testing,

BOX 184.1 Differential Diagnosis of Rabies

Viral-borne encephalitis
 Herpes simplex virus (HSV-1)
 Arboviruses (e.g., Eastern equine encephalitis, Western equine encephalitis, West Nile, Japanese encephalitis, California encephalitis, Rift Valley fever)
 Enterovirus: Enterovirus 71
 Cerebral malaria
 Acute disseminated encephalomyelitis (ADEM)
 Limbic encephalitis
 Guillain-Barré syndrome
 Poliomyelitis
 Post-rabies vaccine encephalomyelitis
 Tetanus
 Botulism
 Drugs
 Direct toxicity: drug-induced psychosis (e.g., phencyclidine [PCP])
 Drug syndromes: serotonin syndrome, neuroleptic malignant syndrome
 Drug withdrawal: severe alcohol withdrawal
 Florid mental illness
 Rabies hysteria

and euthanasia with analysis of brain tissue can be undertaken. Traditional testing requires fluorescein-labeled antibody to detect viral antigens. More recently, enzyme-coupled antibodies have been introduced, allowing colored neuronal inclusions to be observed under the light microscope.¹⁸⁰ RABV RNA also can be detected by dot hybridization or by RT-PCR amplification.¹⁵² Virus isolation may be used for confirmation, either through intracerebral inoculation in mice or by inoculation of neuroblastoma cells with subsequent fluorescent antibody staining for viral antigens. When the animal is unavailable for rabies testing, such as if a bat in a room flies away, or the biting dog is never captured, more involved assessments are required. This is particularly true if the clinical presentation leaves any doubts. The classic clinical expression of rabies in humans is made clear with a history of animal bite exposure, paresthesia at the wound site, and hydrophobia. In fact, in developing countries where advanced laboratory testing is not available, the presence of hydrophobia and aerophobia is considered diagnostic of rabies.^{79,312} The differential diagnosis includes other viral-borne causes of encephalitis, such as from arboviruses, enteroviruses, and herpes simplex virus (Box 184.1). Occasionally cerebral malaria, acute demyelinating encephalomyelitis (ADEM), or other limbic forms of encephalitis may demonstrate significant clinical overlap.²⁴⁶ However, further testing, such as isolation of malaria parasites in the blood, or finding a space-occupying lesion on head imaging, should yield an alternative diagnosis.

Paralytic rabies, conversely, may present special diagnostic challenges. Important differential diagnosis includes Guillain-Barré syndrome, poliomyelitis, or post-rabies vaccine encephalomyelitis. Tetanus is sometimes considered as well, particularly because animal bites and penetrating injuries are tetanus-prone wounds by definition. However, tetanus examination findings, such as sustained muscle spasm and trismus, are not found in rabies.

Botulism (either from a wound or from ingestion) may be more difficult to rule out because drooling may be found with oropharyngeal paralysis, but the absence of sensory changes should exclude rabies. Other important differential considerations include psychosis from drug effects or florid mental illness. In one tragic human case,⁸⁸ a 16-year-old boy was tested repeatedly for drugs, and even went to a psychiatric facility, before hydrophobia was noted and the diagnosis of rabies was finally made.

Relatively new research on encephalitis has shed light on some of the specific causes of this disease.^{19,106,112} This is important because of clinical overlap with rabies encephalitic symptoms, such as in anti-N-methyl-D-aspartate (anti-NMDA) receptor encephalitis. In these

TABLE 184.4 Antemortem Diagnostic Test Results for 62 Human Patients With Rabies: United States, 1960–2010

Test	No. of Patients Positive for Rabies Virus/ Total No. Tested (%)	Earliest Positive (Day of Test Illness)
RT-PCR of saliva for rabies virus RNA	27/32 (84)	2
Brain biopsy for rabies virus antigen	4/6 (67)	7
Nuchal skin biopsy for rabies virus antigen	24/41 (59)	2
Virus isolation from saliva	11/23 (48)	3
Antibody to rabies virus in serum	38/53 (72)	4
Rabies virus antigen in touch impression from cornea	9/19 (47)	2
Antibody to rabies virus in cerebrospinal fluid	17/41 (5)	5

Modified from Petersen B, Rupprecht C. Human rabies epidemiology and diagnosis. In: Tkachev S, ed. *Non-flavivirus Encephalitis*. New York: InTech; 2011.

patients, symptoms include agitation, psychosis, autonomic dysfunction, and other neurologic symptoms. In-depth workup and evaluation are often necessary to identify potential causes. In fact, in up to two-thirds of encephalitis cases in the United States, an underlying cause is never discovered.¹⁹ In the past, postvaccination encephalitis with NTVs was a diagnostic dilemma, yet this is a vanishing disease entity because NTVs are phasing out globally. In addition, rabies hysteria is largely a syndrome of the past, when rabies threats were much more palpable. In this disease, similar to conversion disorder, patients complain of rabies-like symptoms such as hydrophobia, but the examiner’s insights supported by normal laboratory testing can eliminate that diagnostic consideration. Thus, the differential diagnosis of encephalitis may include rabies, and the astute clinician needs to remain vigilant for that possibility. Indeed, nearly one-half of rabies cases are diagnosed post mortem,⁴⁷ a finding suggesting that cases may be missed every year, even in highly developed countries. Multiple transplant-associated rabies cases^{46,137,186,263,291} support such a hypothesis. Thorough history taking, including that from extended family members and friends, careful neurologic examination, and appropriate laboratory analysis (especially of the CSF) are of critical importance, especially in the pediatric patient.

Laboratory diagnosis is possible before death through rabies antemortem rule-out testing. Antemortem rabies diagnosis has increased relevance with the improvement of intensive care and potential new treatment for rabid patients. Such antemortem testing requires a set of four samples: saliva, skin biopsy from the nape of the neck, CSF, and serum.¹³¹ Viral antigens may be demonstrated by fluorescent antibody staining of smears of corneal epithelial cells^{163,249} or sections of skin from the neck at the hairline.^{36,259} Corneal impressions are not routinely used in the presence of modern diagnostic techniques. These test results become positive once virus migrates down the nerves from the brain because both the cornea and hair follicles are richly innervated.

Serologic diagnosis also can be obtained if the patient survives beyond the acute period. In persons not given PEP, only low levels of antibodies appear.^{131,130} In contrast, patients who have received vaccine show a rapid rise in titer of virus-neutralizing antibodies between 6 and 10 days after the onset of symptoms.¹¹⁹ Such antibodies are detected by an in vitro method, such as the rapid fluorescent focus inhibition test (RFFIT) or historically by mouse neutralization tests. Rabies may be diagnosed in immunized persons by a rise in titer after the onset of clinical symptoms and is suggested by any antibody titer 1:5000 or greater, a level not usually achieved by routine vaccination. High antibody levels in CSF are characteristic late in the course of rabies encephalitis; CSF antibody is not induced efficiently by vaccination.^{119,304}

Virus has been isolated from human saliva between days 2 and 24 after onset of disease.^{119,220} Virus also may be isolated in some rare cases from CSF or from concentrated urine sediment during the first 2 weeks of illness. In persons surviving longer than 2 weeks, isolation of virus from body tissues or fluids (or from postmortem brain) may be more difficult, presumably because of virus neutralization by humoral antibody.

Postmortem diagnosis can be confirmed by the presence of pathognomonic cytoplasmic inclusions (Negri bodies) in brain tissue, but

they are present in fewer than 80% of cases. RABV antigens may be detected by fluorescent antibody examination, with higher frequency in brain tissues of persons dying after a brief, acute course of disease. In postmortem tissues, histochemical staining with monoclonal antibody to viral internal antigens especially may be useful because ribonucleoprotein possesses epitopes resistant to the formalin fixation and the paraffin-embedding process.¹⁹⁴ In studies of paraffin-embedded brain tissues (samples up to 40 years old), digestion of sections with proteinase K followed by immunofluorescence or RT-PCR testing gave 100% (300 of 300) positive results.²⁹⁵ TaqMan real-time RT PCR is particularly useful.²⁹²

However, as in the case of virus isolation attempts, identification of viral antigens in brains of persons kept alive for prolonged periods after onset of disease may be extremely difficult.

Petersen and Rupprecht²²⁰ summarized the results of antemortem attempts to diagnose rabies in humans. Their data are summarized in Table 184.4,²²⁰ which shows that RT-PCR analysis of saliva and brain biopsy is the most accurate method of diagnosis; results can be positive as early as the second day after onset. Because of the different times in which antemortem test results can be negative in any of the four required samples (i.e., skin, saliva, serum, and CSF), ruling out of rabies can occur definitively only when all samples taken at the same time test negative. Serial sampling may be required if other etiologic explanations fail.

PROPHYLAXIS

Local Wound Management

Human rabies is virtually 100% preventable after an exposure. The immediate washing of a wound after an animal bite or scratch is a crucial part of PEP. These wounds are contaminated with saliva that contains virus and should be flushed copiously with soap and water, for no less than 10 to 15 minutes. This immediate lavage helps to reduce viral load, thus leading to increased survival after exposure in 50% of patients, and this inexpensive but effective intervention is especially useful in medically underserved health care settings.^{153,298} Some investigators suggest an additional local application of povidone-iodine or ethanol. The concentration of ethanol is important: 43% (86 proof) or higher gave the best results.³¹⁵

Experimental data suggest that regardless of the solutions used, thorough irrigation and flushing are important, particularly in deep puncture wounds. Catheters should be inserted into puncture wounds and fluid instilled by means of an attached syringe.^{67,256} If this procedure proves to be too painful, the area may be anesthetized safely with local procaine-type anesthetic agents.^{153,315} Suturing should be done only in line with good surgical practice and limited as much as possible to minimize the opportunity for driving virus deeper into surrounding tissues.³²²

Passive Immunity

The administration of rabies immune globulin (RIG) is an essential component of PEP in a previously unimmunized patient. The delivery

of antibodies enables immediate virus neutralization at the site of injury while the active immune response from rabies vaccination starts to mature. The production of endogenous antibodies induced by rabies vaccination may take at least 7 days or more to reach adequate levels. Thus, RIG should be used only up to 1 week after the first rabies vaccine is given. RIG is never used in patients previously vaccinated against rabies because this may mute the body's normal immune response. Instead, for those patients previously vaccinated, booster doses of vaccine on days 0 and 3 are given per Advisory Committee on Immunization Practices (ACIP) and WHO guidelines.^{28,114}

The role of passive immunity in saving lives after exposures had been demonstrated under field conditions, and it is more relevant when a short rabies incubation period is presumed, such as in head and neck exposures.^{97,115} Despite the WHO recommendation of RIG use as part of routine PEP, it is still rarely used in most of the developing world. Delayed initiation of PEP because of limited health care access may allow progression of viral infection. In these cases, the use of RIG should not be ignored because of the increased risk for prophylaxis failure. In other words, there could still be a significant benefit from RIG, regardless of the time between exposure and presentation for PEP.²⁹⁸

Two major formulations of RIG are available: human (HRIG) and equine (ERIG). The former is more expensive to produce and is available mostly in the developed world, whereas ERIG is certainly less costly and is found in the developing world where available.³²⁰ Often, however, even ERIG is unavailable in resource-constrained countries.

As an alternative to RIG, virus-specific monoclonal antibodies (MAbs) have been developed that would provide an economical and more readily available product.⁷⁴ Clinical studies are ongoing in animals and humans.^{15,68,254} Such MAb formulations would likely improve access to passive immunity.^{15,28,68,206}

Equine Rabies Immune Globulin

Animal rabies serum is no longer available in the United States and most developed countries. Previous versions of this chapter go into more detail regarding the use and history of ERIG.^{174,223,247,321,318,319}

Human Rabies Immune Globulin

HRIG is prepared from the fractionation of gamma globulin (immunoglobulin G [IgG]) from the plasma of volunteers hyperimmunized with rabies vaccine. HRIG is currently the standard in the United States for immediate passive immunity in rabies PEP.¹⁸⁷ Because the gamma globulin is homologous in humans, HRIG persists for longer in the circulation compared with ERIG, which obviously is an animal protein. For this reason, HRIG may have a greater dampening effect on active immunization compared with ERIG. This factor may not be relevant, however, given the excellent quality and potency of modern-day rabies vaccines.

Dosing of HRIG derives from pharmacokinetic measurements,^{120,125,185,193,236} such that 20 IU of HRIG per kilogram should be administered immediately, with as much as possible being injected locally. The remainder can be injected at a distal site intramuscularly, away from the vaccine administration site. Local HRIG injection is extremely important (Fig. 184.3) because serum levels of antibody after intramuscular injection are not high.⁵⁴ Although intravenous administration of HRIG produces higher serum titers,⁵ local injection is still preferred. No further dose is necessary or desirable because excessive antibody diminishes the active response to vaccine. Two equivalent preparations of HRIG are available in the United States, one produced by Sanofi Pasteur (Imogam Rabies-HT, Sanofi Pasteur) and the other by Grifols (HyperRAB S/D, Grifols). If HRIG is unavailable, vaccination should be started immediately, followed by administration of HRIG if it arrives within a week.¹⁵⁸

Nerve Tissue Vaccines

NTVs revolutionized rabies prevention after the introduction of the original Pasteur vaccine. However, NTVs have been replaced by cell culture vaccines in developing countries. NTVs produced in sheep or goat brain were widely used throughout Asia and Africa but were associated with a high incidence of postvaccine encephalitis.⁷ The previous version of this chapter goes into greater detail regarding NTVs^{105,222} and

FIG. 184.3 Injection of human rabies immunoglobulin after a savage attack by a stray cat.

duck embryo vaccines,^{157,235,248} which were designed as a replacement yet are now considered obsolete in the developed world.²²³

Cell Culture Vaccines

Rabies immunization evolved further with the development of safe and potent cell culture vaccines. RABV grown in cell culture is by definition free of neural tissue. Choosing a human cell line for growth avoids issues with foreign host proteins that could cause serious adverse events. The first widely used cell culture vaccine was the human diploid cell vaccine (HDCV). A human fibroblast cell line (WI-38) was developed,¹²³ and the Pitman-Moore strain of RABV was grown in these cells by Wiktor and associates.³¹³ Subsequently, the virus was harvested and concentrated by ultrafiltration to increase antigen content. Inactivation was performed with β -propiolactone. After various schedules of HDCV were compared, researchers found that three properly spaced intramuscular doses consistently produced a robust immune response.¹⁴ A similar schedule of duck embryo vaccine resulted in antibody titers 10 to 20 times lower. The excellent immunogenicity of HDCV was confirmed,^{6,37,64,108,187,226,283,317} and it became a gold standard against which other vaccines were measured.

A crucial test of any rabies vaccine is protection of those actually exposed to the virus. In Europe, the HDCV was used to vaccinate thousands of people exposed to rabies. However, those situations in which rabies was confirmed in the biting animal were particularly important to consider. Kuwert and associates^{167,168} in Essen, Germany, vaccinated 68 persons after exposure to dogs, cats, cows, or wild animals with laboratory-confirmed RABV infection or exposed as a result of a laboratory accident. The schedule used was 1 mL intramuscularly on days 0, 3, 7, 14, 30, and 90. These investigators had no failures of protection, no significant reactions, and excellent neutralizing and complement-fixing antibody responses.

Bahmanyar and associates¹⁴ in Iran conducted another test of HDCV. Forty-five persons who were bitten by rabid wolves or dogs were given rabies antiserum, followed by the same schedule of vaccine used in Germany. Once again, no rabies cases developed in vaccinees, despite an estimated 40% risk of disease if they had remained unvaccinated. Antibody measurements showed mean titers as follows: 7 days, 1.1 IU; 14 days, 10.7 IU; 30 days, 49 IU; and 100 days, 312 IU.

Later, the CDC distributed HDCV of US manufacture for persons whose exposure to rabies was established.³ No vaccine failures occurred, and all healthy persons who received the full schedule of five 1-mL doses intramuscularly responded with antibodies, to date.

Although a few vaccine failures have been reported in other countries after administration of HDCV, ancillary prophylaxis recommendations were not followed scrupulously in each case.⁴ The failure rate is estimated to be at most 1 in 12,000 courses of vaccination given in countries with a high risk for rabies.²¹² General anesthetic agents given locally while the wound is repaired may increase the risk for vaccine failure.⁹⁵ The exact mechanism of protection afforded by PEP is uncertain. It may be blockage by antibodies of virus passage from subcutaneous tissue to the CNS, or it may actually be through the induction of innate and adaptive immune responses in parts of the CNS.^{135,181}

An effort has been made to produce vaccines with the desirable properties of HDCV at a lower cost that would make them broadly available in developing nations, where the risk for human rabies is most severe. For example, purified Vero cell rabies vaccine (PVRV) is the Pasteur strain of RABV (as used in HDCV) grown in a Vero cell line in industrial fermenters. The virus is concentrated, inactivated, and purified. The PVRV has an immunogenic potency similar to that of HDCV. Successful PEP experiences have been reported in multiple countries, including Tunisia,⁵⁰ China,²⁹⁴ and Thailand, even after severe exposure.^{144,268,304} The PVRV has been purified further by chromatography.¹⁷⁵

Purified chick embryo cell (PCEC) rabies vaccine is produced in primary chick embryo cell culture with use of the Flury low egg passage strain of RABV. It is inactivated, concentrated, and purified, yielding a vaccine preparation of antigenic potency similar to that of PVRV and HDCV.¹⁸ The PCEC rabies vaccine was uniformly successful in preventing rabies in PEP trials in the former Yugoslavia, including subjects who were exposed by wolf bite.^{61,289} The PCEC rabies vaccine also was shown to be equivalent to HDCV for PEP,²²⁹ for boosting previously immunized subjects,³³ and in animal models for protection against bat rabies virus variants.⁷⁵

Two types of rabies vaccine are now licensed and available in the United States: HDCV and PCEC. A tissue culture vaccine made in fetal rhesus diploid cells previously by the Michigan State Department of Health (and later Bioport), termed rabies vaccine adsorbed (RVA), is no longer distributed.²⁰ Either HDCV or PCEC rabies vaccine is recommended for PEP when given by the intramuscular route according to the regimens listed in Table 184.5. In 2011, the PEP regimen in the United States was reduced from five to four intramuscular doses in those with a normal immune system, in recognition of the high immunogenicity of the vaccines. Immunosuppressed patients should continue to receive five doses.²³⁷ Decreased immune responses have been noted in vaccinees given injections in the gluteal area,⁹⁸ and therefore all intramuscular injections of rabies vaccine should be given in the deltoid muscles. In the event of repeat exposure of persons with a prior history of vaccination, two intramuscular booster doses should be given (see Table 184.5). Virtually 100% of these patients will have an anamnestic response.²⁷⁰

Numerous regimens have been developed for rapid immunization of exposed patients in developing countries who may seek medical help late or who may not return for subsequent doses.^{269,290,304} To reduce costs, intradermal administration is often used because of the smaller volume required, which enables cost sharing of a standard dose among vaccinees. Moreover, because appropriate follow-up of patients for subsequent doses is more erratic in developing countries, the intradermal schedules generally are relatively short.^{116,255,300,301} Some workers propose a 1-week schedule.^{196,266} These regimens are listed in Table 184.5 and have the advantage of being less expensive. Note that if the 2-1-1 regimen is chosen, RIG may interfere with the body's native response to the vaccine.³¹²

No intradermal rabies vaccine schedule is licensed in the United States,¹⁸⁷ partly because of the scarcity of mass exposures, the lack of bite clinics, and a relative inexperience with such delivery. Indeed, there is a small risk of failure with improper administration because intradermal vaccination requires some skill, given the millimeter depth of the dermis.

The effectiveness of current rabies vaccines to protect against most rabies-related lyssaviruses appears to be adequate; however, for those viruses in phylogroups II or III, there may be no protection afforded.^{111,205}

Clinical Considerations

Decisions to Immunize

A physician must weigh numerous factors in deciding when to immunize a patient against rabies (Table 184.6). Some important considerations include the type of animal involved, the biting or exposure incident, the geographic area, patient-related factors such as immunosuppressive medications, or pregnancy. Costs, potential adverse events, pain, and inconvenience also need to be balanced against risk. With rabies, clinicians tend to favor overt vaccination, given the fatal nature of the disease. In fact, a study in the United States²⁰¹ revealed that rabies prophylaxis was inappropriately administered in 40% of cases. However, the study also showed that 6% of those not receiving prophylaxis should have received it. Thus, physician education regarding rabies certainly needs improvement.²³³

Pregnancy

The modern cell culture rabies vaccines are considered safe in pregnant women.^{58,265} In the developing world, the issue of saving the unborn child of an expectant mother with rabies has occurred, and healthy infant delivery has been reported. Because rabies viremia is not known to occur, and a maternal-fetal barrier exists (the placenta), experts favor urgent cesarean section to save the child if feasible. The infant usually would not require rabies prophylaxis to ensure survival. However, data and evidence-based medicine available to provide guidance in such a rare clinical circumstance are not available, and each case should be

TABLE 184.5 Regimen Examples for Preexposure and Postexposure Vaccination With Rabies Vaccines

Vaccination	Route	Days on Which Doses Are Given	Remarks
Preexposure	IM ^a	0, 7, 21, or 28	Standard US and WHO three-dose regimen Economical, but not to be used in those taking antimalarial medications; unlicensed route in United States; WHO recommended
	ID ^b	0, 7, 21, or 28	
Postexposure ^c	IM ^a	0, 3, 7, 14	Standard US four-dose recommendation
	IM ^a	0 (2 doses), 7, 21	Used in some countries when RIG is not indicated; so-called 2-1-1 schedule
	ID ^b	0, 3, 7 (2 doses each), 28	Used in Thailand with PVRV, PCECV; so-called 2-2-2-0-1 schedule
	ID ^{b,d}	0 (8 doses), 7 (4 doses), 28, 90	Used in developing countries with HDCV, PCECV, or PVRV cell culture vaccines; so-called 8-0-4-0-1-1
Booster (for reexposure)	IM ^a	0, 3	Only after documented vaccination with cell culture vaccine ^e
	ID ^b	0, 3	Only after documented vaccination with cell culture vaccine ^e

^aTogether with rabies immunoglobulin.

^bGive 0.1 mL, over the deltoids.

^cGive 0.5 mL (PVRV) or 1 mL, depending on the vaccine, into the deltoid.

^dGive 0.1 mL at multiple sites (see text).

^eOr demonstrated presence of virus-neutralizing antibodies after other vaccines.

TABLE 184.6 Rabies Postexposure Prophylaxis Guide: United States

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 days of observation	Persons should not begin prophylaxis unless animal develops clinical signs of rabies ^a
	Rabid or suspected rabid	Immediately vaccinate
	Unknown (e.g., escaped)	Consult public health officials
Skunks, raccoons, foxes, and most other carnivores; bats ^b	Regarded as rabid unless animal proven negative by laboratory tests ^c	Consider immediate vaccination
Livestock, small rodents, lagomorphs (rabbits and hares), large rodents (woodchucks and beavers), and other mammals	Consider individually	Consult public health officials. Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares almost never require antirabies postexposure prophylaxis.

^aDuring the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.

^bPostexposure prophylaxis should be initiated as soon as possible after exposure to such wildlife unless the animal is available for testing and public health authorities are facilitating expeditious laboratory testing or it is already known that brain material from the animal has tested negative. Other factors that may influence the urgency of decision making regarding initiation of postexposure prophylaxis before diagnostic results are known include the species of the animal, the general appearance and behavior of the animal, whether the encounter was provoked by the presence of a human, and the severity and location of bites. Discontinue vaccine if the result of an appropriate laboratory diagnostic test (i.e., the direct fluorescent antibody test) is negative.

^cThe animal should be euthanized and tested as soon as possible. Holding for observation is not recommended.

individualized when the need for rabies prophylaxis in the newborn exposed to maternal rabies is considered.

Exposures to Bats, Wildlife, and Domestic Animals

In the United States, significant rabies reservoirs are found in multiple species of wildlife.²⁰⁰ Bats and rabies are a special problem, as earlier discussion in this chapter has highlighted. When in doubt, bat testing in the setting of possible human exposures is the best way to rule out any risk of RABV transmission.¹⁸⁷

Wild carnivores such as raccoons, skunks, and foxes involved in exposures must be considered rabid until proven otherwise. Rodents, with the exception of woodchucks and possibly beavers, are unlikely to be rabid.²⁰⁰ Cat bites and cat scratches need important consideration, especially because rabid cats have consistently outnumbered dogs over the years by several factors. Cat immunization rates are lower compared with dogs, and cats may engage in more free-roaming activity wherein they may acquire infection. Cats always are suspect if they go out of their way to bite. Dog exposures, conversely, are less worrisome, given the successes of public health measures in recent times. This concept may not apply, however, for dogs residing close to the US-Mexican border, where circulating wildlife (gray fox) strains present a potential for reintroduction in nonimmunized animals.¹⁸⁷

Circumstances of Bite

Clinical consideration of a provoked versus an unprovoked animal attack deserves some attention. For example, an attempt to feed an undomesticated animal is considered provocative behavior. Invasion of an animal's space or territory may be seen as a threat. This normal behavior for the animal is therefore less concerning for rabies compared with a spontaneous attack by an animal in a human environment. In rabies-endemic areas, however, this concept of a provoked versus unprovoked attack is poorly predictive of rabies.¹⁶⁵

If an animal appears clinically rabid, it should be euthanized immediately for confirmation of rabies by brain examination. If a dog, cat, or ferret appears normal, it may be kept for 10 days to see whether it develops rabies.¹⁹⁷ Clinical judgment about whether to start rabies prophylaxis depends on factors including the prevalence of rabies in the particular region, the species of animal, and the circumstances of the incident.

Rabies is extremely rare in properly vaccinated animals, yet it can occur.²⁰⁰ Thus, prophylaxis may be administered if clinical or epidemiologic data suggest rabies, even in a vaccinated animal.

Table 184.6 summarizes recommendations by the ACIP on vaccination against rabies.¹⁸⁷ Advice can be sought from state and local health

departments (particularly with regard to the occurrence of rabies in animals) and from the CDC directly.

Failure of Rabies Prophylaxis

The most common causes of human rabies are that no prophylaxis was given, a delay in PEP occurred, or there was a deviation from protocol such as the improper use of RIG.^{70,107,322} Active immunization with vaccine does not regularly produce antibodies until 7 to 14 days after the first dose is given, hence the need for RIG for immediate passive protection. RIG is best given locally around the wound. If a large area is needed, the product can be diluted with saline.³²² Additionally, certain diseases and drugs such as chloroquine may exert an immunosuppressive effect and may account for other failures. The presence of B-cell immunodeficiency in a patient requires measurement of antibodies (titers) after vaccination. Patients infected with human immunodeficiency virus (HIV) are likely to respond if their CD4⁺ lymphocytes are higher than 300/ μ L. If not, their postvaccination antibodies also should be measured.¹⁴⁴ In HIV-infected children, a standard PEP course of HDCV had no effect on the level of CD4⁺ lymphocytes or the HIV-1 viral load.²⁷⁵ However, even with correct prophylaxis, failures may occur, perhaps because in severe exposures, virus is deposited directly onto nerve endings.¹²⁹ Failures of the health care system such as inadequate monitoring of vaccine and RIG potency in developing countries may also be implicated.¹¹

PREEXPOSURE IMMUNIZATION

Human rabies is 100% preventable with appropriate preexposure immunization. Modern vaccines are highly effective in persons at risk of exposure. Veterinarians, animal handlers, laboratory workers, and spelunkers should receive preexposure immunization (Table 184.7). Large numbers of veterinary students have been vaccinated under a three-dose schedule at 0, 7, and 21 or 28 days. Rabies virus antibody titers were determined on the serum of each veterinary student. Nearly 100% developed antibodies, with geometric mean titers of 10 IU or greater, which is equivalent to a neutralizing antibody titer of at least 1:200.²³² The three-dose regimen listed in Table 184.5 induces antibodies in 100% of healthy recipients. Preexposure immunization may be given with the use of HDCV and PCEC rabies vaccines by intramuscular administration. Outside the United States, any of the alternative cell culture vaccines on the WHO preapproved list can be used on the same schedule.²⁴⁴ In addition, economic considerations may lead to immunization by the intradermal route, according to the same schedule.³⁰⁵

TABLE 184.7 Rabies Preexposure Prophylaxis Guide: United States

Risk Category	Nature of Risk	Typical Populations	Preexposure Recommendations
Continuous	Virus present continuously, often in high concentrations	Rabies research laboratory workers ^a	Primary course
	Specific exposure likely to go unrecognized Bite, nonbite, or aerosol exposure	Rabies biologics production workers	Serologic testing every 6 months; booster vaccination if antibody titer is below acceptable level ^b
Frequent	Exposure usually episodic with source recognized, but exposure also could be unrecognized Bite, nonbite, or aerosol exposure	Rabies diagnostic laboratory workers, ^a cavers, veterinarians and staff, and animal-control and wildlife workers in areas where rabies is enzootic All persons who frequently handle bats	Primary course; serologic testing every 2 y; booster vaccination if antibody titer is below acceptable level ^b
Infrequent (greater than in population at large)	Exposure nearly always episodic with source recognized	Veterinarians and animal-control and wildlife workers in areas with low rabies rates	Primary course
	Bite or nonbite exposure	Veterinary students Travelers visiting areas where rabies is enzootic and immediate access to appropriate medical care, including biologics, is limited	No serologic testing or booster vaccination
Rare (population at large)	Exposure always episodic with source recognized Bite or nonbite exposure	US population at large, including persons in rabies-epizootic areas	No vaccination necessary

^aJudgment of relative risk and extra monitoring of vaccination status of laboratory workers are the responsibilities of the laboratory supervisor.

^bMinimum acceptable antibody level is complete virus neutralization at a 1:5 serum dilution by the rapid fluorescent focus inhibition test, equivalent to ~0.1 IU/mL. A booster dose should be administered if the titer falls below this level.

From Manning SE, Rupprecht CE, Fishbein D, et al; Advisory Committee on Immunization Practices Centers for Disease Control and Prevention (CDC). Human rabies prevention—United States, 2008: recommendations of the Advisory Committee on Immunization Practices. *MMWR Recomm Rep* 2008;57:1–28.

Because rabies in developing countries is primarily a disease of children, exploratory studies have been performed to determine whether preexposure vaccination could be incorporated into routine pediatric schedules. Preliminary results from Vietnam show that routine rabies vaccination in infancy is feasible,¹⁷⁶ and it could even be performed by low-dose intradermal administration.⁸³ In areas enzootic for canine rabies, universal vaccination of children could be cost effective if the incidence of dog bite is high.⁵⁷ Children at routine risk for vampire bat exposures throughout Amazonia should be considered as well for preexposure vaccination. Children infected with HIV can be immunized successfully if their CD4⁺ cells exceed 15% of lymphocytes. Those children with fewer CD4⁺ cells may need at least double doses of rabies vaccine.²⁷⁵ Missionaries and Peace Corps personnel operating in rabies-endemic countries should receive preexposure vaccination.⁹

Intradermal Vaccination

For preexposure use, the intradermal route is considered an acceptable alternative to intramuscular injection, with the important proviso that persons receiving antimalarial or other immunosuppressive agents and perhaps older persons should have their titers checked after vaccination or receive the injections by the intramuscular route. The success of intradermal vaccination depends on a technique that ensures intradermal rather than subcutaneous injection, but a margin of error exists.^{21,97}

Today, essentially all intradermal vaccinations abroad are done with PVRV and PCEC rabies vaccine. To reduce the costs of vaccination, intradermal vaccination for postexposure use has become popular in developing countries, but it is no longer approved in the United States. Although single-dose preparations are not available for the intradermal administration of the 0.1-mL dose, extensive experience in Thailand and elsewhere has validated the successful prevention of rabies with vaccine extracted from vials intended for intramuscular use.^{83,282,303,306} However, attention must be paid to the correct administration of the dose into the skin, the sterility of unused portions of the vial for only a few hours while maintaining the cold chain, the volume of vaccine in the ampule, and the antigenic content of the vaccine used. The antigenic content should be at least 0.25 IU/0.1 mL. A popular intradermal schedule is one developed by the Thai Red Cross, consisting of inoculations on days 0, 3, 7, and 28 days, with double doses given in the first three administrations. A former recommendation for a 90-day dose has been abandoned.¹⁵⁹ Poor responses to intradermal vaccine

have been noted in those concurrently receiving chloroquine or immunosuppressive agents, such as corticosteroids.^{187,216} Therefore, persons who must be vaccinated while they are taking chloroquine or related antimalarial agents should be given injections into the deltoid muscle, and postvaccination rabies serologic studies should be obtained on those patients and others who are immunosuppressed.

Alternative Schedules

Although the WHO schedules are firmly established for the induction of optimal immune responses, other schedules have been tested extensively to reduce the number of vaccination visits, particularly in the developing world. One of the most popular of these is the 2-1-1 schedule, in which a double dose is given intramuscularly at day 0, followed by single doses on days 7 and 21,^{59,195} and the regimen developed by Warrell and associates,³⁰³ consisting of eight intradermal doses on day 0, four intradermal doses on day 7, and single doses on days 28 and 90.

The 2-1-1 schedule may not be as reliable if immunoglobulin (RIG) is administered.^{173,176}

Booster Doses

Even with administration of cell culture vaccine, antibodies fall off rapidly after initial immunization, although most vaccine recipients have some detectable antibody decades after initial vaccination.^{89,151} Nonetheless, once an immune response to rabies vaccine has developed, revaccination is almost certain to evoke a rapid response.²⁷⁰ One booster of cell culture vaccine given to previously vaccinated persons results in a dramatic anamnestic response, with titers in one study rising from 2.8 to 94 IU at 14 days and more than 100 IU in 35 days.²²⁵ As mentioned, with exposure to rabies in a previously vaccinated person, two intramuscular booster doses are recommended to provide a margin of safety. Single intramuscular or intradermal boosters are given to maintain immunity in individuals chronically exposed to rabies, according to the recommendations made by the ACIP and WHO in Table 184.7 if serologic testing suggests a waning titer.

In persons who have received preexposure immunization to rabies, the necessity of boosters is an important issue. Persons who definitely were exposed to a rabid animal should receive two booster doses of vaccine by the intramuscular route. Individuals who are likely to be exposed to actual virus, such as rabies laboratory workers, should be bled every 6 months and receive booster injections as needed to maintain their antibody titers above 0.5 IU (or complete neutralization at a

dilution of 1:5, equal to ~0.1 IU/mL). A follow-up study by Briggs and Schwenke³⁴ found maintenance of an adequate titer (>0.5 IU) at 1.5 to 2 years after vaccination in 99% of subjects who received vaccine by the intramuscular route and in 93% who received vaccine by the intradermal route. In Thailand, researchers demonstrated that persons who received preexposure rabies vaccination by the intradermal route mounted a slow response to boosters, and the investigators suggested that in severe exposures, rabies RIG should be given despite the prior immunization.¹⁴⁴ However, the intradermal route can be used successfully to boost prior immunity.²⁷² Thraenhart and associates²⁷⁷ observed 100% of antibodies induced in 18 subjects studied between 2 and 14 years after they received vaccination. Thus, if a person is properly vaccinated with modern cell culture vaccines, subsequent administration of RIG is not indicated in PEP.

Adverse Events

The available tissue culture vaccines are well tolerated. In more than 1770 human volunteers receiving preexposure immunization with HDCV administered intramuscularly, a sore arm was noted in approximately 20%, headache in about 8%, malaise in 5%, and allergic edema in 0.1%.²²⁵ During incidents involving mass PEP, pain, swelling, and other local symptoms occurred in 30% to 74% of individuals.¹⁸⁷ Pregnancy is not a contraindication to receiving modern rabies vaccines.⁵⁹ Guillain-Barré syndrome and other neurologic problems have been rare occurrences, and their relationship with HDCV is uncertain.¹⁶¹ Guillain-Barré syndrome that occurs after administration of NTV is associated with antibodies to myelin basic protein.¹²⁷

In contrast, booster vaccinations with HDCV have been associated with allergic reactions in approximately 6% of subjects.⁴² Those reactions were believed to be caused by the presence in the vaccine of human albumin that has been altered by the β -propiolactone used to inactivate the virus.^{3,271,307} The reactions are of the immune complex type (type III), with urticaria, edema, joint manifestations, fever, and malaise. CDC data suggest that when primary vaccination is given intramuscularly and booster intradermally, or vice versa, reactions are more common than if all vaccination is by the same route.⁹⁹ Because the reaction is associated with the particular formulation of HDCV rather than with the virus antigen itself, additional boosters may be given if necessary with PCEC rabies vaccine, PVRV, or HDCV manufactured in Canada (Sanofi Pasteur).⁹⁶ Reactions to PVRV and PCEC cell culture vaccines generally have been mild.⁸¹ A comparative study of PVRV with HDCV showed lower or equivalent rates of local and systemic reactions, with no serious adverse events.¹⁵⁰ Because PCEC rabies vaccine is manufactured in chicken cells, egg allergy is a possible problem, and anaphylactic events as well as some rare and perhaps unrelated neurologic complications have been reported.

FUTURE DEVELOPMENTS

Rabies, both the disease and progress in its prevention, is far from static. For example, Table 184.8 shows the progress of rabies vaccine development for humans. Perhaps the most dramatic future prospect is the development of vaccines in which the gene for RABV glycoprotein has been inserted into a viral vector, such as a poxvirus or adenovirus, or the use of rabies virus as a cloning and expression vector system by reverse genetics.^{38,243} These vaccines already have been used extensively in a large variety of animal species, in which they have been found to be safe and highly immunogenic.²³⁹ In field studies, raccoons and other wild animals have been immunized successfully by the oral route with baits containing rabies recombinant vaccines. Such vaccination has eliminated fox rabies from large areas of Western Europe³⁰ and has reduced raccoon rabies in the eastern United States.^{240,257,258} Other avenues being pursued include the use of potent adjuvants to enhance the immunogenicity of subunit vaccine,⁹⁴ the addition of the internal ribonucleoprotein to enhance protection through induction of cellular immune responses and higher antibody responses,²⁷⁸ synthetic peptides constructed from epitopes of the single glycoprotein and nucleoprotein,⁷³ and plasmid vectors containing cDNA of the glycoprotein (G protein) gene.³²⁸

TABLE 184.8 Examples of Rabies Vaccines Tested in Humans

Vaccine Types	Remarks
Pasteur: dried rabbit spinal cord	Residual live virus; NLU
Fermi: phenolized sheep or goat brain	Residual live virus; NLU
Semple: phenol-inactivated sheep or goat brain	Contains nerve tissue; NLU
Fuenzalida-Palacios: phenol-inactivated suckling mouse brain	Contains less myelin; once used extensively throughout Latin America
Duck embryo: BPL inactivated	Allergy to duck proteins
Human diploid cell (HDCV): BPL-inactivated fetal human cell culture vaccine	First tissue-culture standard; booster allergic reactions
Rabies vaccine adsorbed (RVA): fetal rhesus cell culture, BPL inactivated	Fewer allergic reactions; no longer marketed in United States
Vero cell (PVRV): BPL-inactivated virus	Purified by density gradient centrifugation; grown in Vero monkey kidney cell line
Chick embryo cell (PCEC rabies vaccine): inactivated virus grown in chick embryo cells	Purification similar to PVRV
Avipox recombinant-glycoprotein (V-RG): genetic construct expressing rabies virus glycoprotein	Limited clinical trials

BPL, β -Propiolactone; NLU, no longer used.

Particular effort has been directed toward the development of DNA vaccines. They are alleged to be potentially inexpensive and particularly thermostable, but to date most have required an unsatisfactory interval to produce virus-neutralizing antibodies or to have induced virus-neutralizing antibodies of inadequate titer.^{182,183,184} Dogs given two doses of Pasteur strain G protein DNA, administered intramuscularly, were shown to develop virus-neutralizing antibodies to rabies and to European bat lyssaviruses 1 and 2 and to have protection against virus challenge.²¹⁹ Jallet and colleagues¹⁴⁵ produced chimeric G DNAs of rabies and EBLV1, or rabies and Mokola virus, to generate vaccines designed to induce virus-neutralizing antibodies in dogs to either all European lyssaviruses or all African lyssaviruses, respectively. In primates, rabies G DNA induced virus-neutralizing antibodies only if it was administered by gene gun.¹⁸⁴

Other approaches have included efforts to express rabies G protein in yeast cells, which failed,²⁷⁶ and in baculovirus in insect cells, which was successful. Although it is less glycosylated than the virion G protein, the baculovirus-expressed G-protein-induced virus-neutralizing antibodies efficiently in mice; its immunogenicity was not improved by adding baculovirus-expressed rabies nucleoprotein (N protein).⁸² In approaches using the rabies G protein cloned into adenovirus, researchers have shown that a replication-defective recombinant elicited enzyme-linked immunosorbent assay antibodies in mice inoculated onto mucosal surfaces,³²⁷ and an adenovirus incorporating a special promoted-intron expression cassette efficiently induced rabies G protein in cell culture that induced virus-neutralizing antibodies in intraperitoneally inoculated mice.¹⁹¹ The rabies G-protein gene was cloned into canine herpesvirus; this recombinant induced virus-neutralizing antibodies efficiently in dogs inoculated by the intranasal route, a finding suggesting that it may be useful as an oral product to control canine rabies.³²⁹ Similar hopes are offered by a new recombinant canine adenovirus vaccine, but widespread infection by canine adenoviruses may preclude such a possibility.

Molecular biologic approaches have not yet produced an ideal vaccine, especially for human use. In the near future, the most cost-effective and protective vaccines may be virion products propagated to high titer in an easily managed cell culture system (e.g., a suitable BHK-21 continuous cell line or transgenic plants).¹⁹⁹ In addition, MAbs may offer effective alternatives to HRIG.^{110,117,228}

More recent work has shown potential for a broadly acting antiviral compound, favipiravir (T-705), to make an impact in rabies PEP.³³⁰ A significant 3- to 4-log₁₀ reduction in viral multiplication in a mouse model was shown. The agent reduced viral positivity in the brain but was thought to be most effective before neuroinvasion occurred, at about an effect equal to ERIG in PEP. Dr. Hilary Koprowski, considered by many as a leading authority on rabies, envisaged possible human rabies treatment in the 21st century, although acknowledging the great challenges.¹⁶⁴

Regardless of developments in human medicine, the key to future progress is a focus on elimination of canine rabies, with greater global partnerships from a One Health perspective.^{192,326}

SUBSECTION IX Arenaviridae and Filoviridae

185

Lymphocytic Choriomeningitis Virus

Rémi N. Charrel • Xavier de Lamballerie

Lymphocytic choriomeningitis virus (LCMV) is maintained in nature through persistent infection of its reservoir host, the common house mouse (*Mus musculus*). Human infection occurs through direct contact with infected rodents or by inhaling infectious rodent excreta or secretions. Although infection with LCMV usually is asymptomatic or mild and self-limiting, it can be severe and manifest as meningitis and encephalitis. Infection during pregnancy may cause fetal loss or congenital malformations.

HISTORY

In the 1930s, LCMV was discovered, at about the same time and independently, in three different localities in the United States. Armstrong and Lillie encountered the agent in a monkey when they passaged a recent isolate of St. Louis encephalitis virus.⁶⁻⁹ In 1935, Rivers and Scott⁶³ described the first two cases of human infection with LCMV. Both these

patients developed febrile illnesses characterized by headache, vomiting, and stiff neck; lumbar puncture revealed 720 and 1700 cells/mm³, nearly all of which were lymphocytes. These investigators subsequently isolated five strains from patients with meningitis.⁶³ Traub⁷¹ revealed the virus in a colony of albino mice. Mice were incriminated in these first isolations, and later observations proved beyond a doubt that *M. musculus* is the principal reservoir of LCMV in nature. However, not until 2007 was definitive evidence presented that LCMV-infected rodents caused disease in humans, as established by genetic comparative analysis.³² For some time after its discovery, LCMV was regarded as the sole etiologic agent of Wallgren acute aseptic meningitis. However, it became clear that Wallgren syndrome had a multitude of viral causes, among which LCMV was of little relevance. In the years after other etiologic agents of acute aseptic meningitis were identified, such as enteroviruses, mumps, or herpesviruses, LCMV progressively disappeared from the sight of virologists and general practitioners. This situation is exemplified by the low numbers of human cases or outbreaks of LCMV infection reported in the medical literature (<80 articles). Meanwhile, LCMV was used as an excellent model for the study of a variety of phenomena of biologic and medical relevance, such as immunologic tolerance, viral immunopathology, slow viral diseases, and latent viral infections, the last demonstrated by the large number of scientific articles on that topic (>3700 references in the PubMed bibliographic database found using “lymphocytic choriomeningitis” as the search criterion).

EPIDEMIOLOGY

LCMV belongs to the genus *Arenavirus*, family *Arenaviridae*. *M. musculus* (the common house mouse) constitutes the reservoir of LCMV in nature, but hamsters also can carry the virus. Humans usually become infected through direct contact with infected rodents or by inhaling infectious rodent excreta or secreta during occupational exposure (laboratory workers, rodent sellers) or household exposure (pet owners). The epidemiologic features vary when animals other than *M. musculus* are involved. Thus, LCMV transmitted from Syrian hamsters has occurred in areas where infected mice are not found. Altogether, 47 human cases have been traced to these pets and may have caused family outbreaks but no epidemics.

Human infection with LCMV is a rare occurrence. Specific tests conducted with diagnostic materials from several large hospitals revealed an incidence seldom exceeding one case per year.⁶⁴ Because *M. musculus* is the reservoir from which most human infections can be traced, efforts were made to clarify the geographic distribution of LCMV-carrying mice. Of 1795 house mice trapped in Germany, 65 carried the virus.¹ In 44 of 376 trapping areas, infected mice were found; these 44 positive sites were unevenly distributed, with a majority located in northern and northwestern Germany. Recently 2 of 37 *Mus musculus* juveniles trapped in French Guinea were found to be infected with LCMV.⁴⁴ In 2015, LCMV RNA was detected for the first time in Africa from *Mus musculus*.³⁷ Together, all these results indicate sustained worldwide presence of LCMV.

In a serologic survey, the proportion of people with LCMV-specific antibodies was significantly higher in rural areas where infected mice were known to live as compared with zoonosis-free districts. In areas where LCMV-carrier mice are frequently found, 9.1% of the rural population had neutralizing antibodies. In contrast, only 1.2% of the people residing in southern Germany, which is essentially free of LCMV-carrying mice, had neutralizing antibodies. Extrapolating from these statistics, approximately 1000 persons are newly infected each year in Germany. Thus, researchers estimate that in western Germany, at least 72,000 persons must have had an infection with LCMV, based on an average life expectancy of 70 years and an approximate rate of new cases of 1000 per year. If this estimation is correct, most infections are not diagnosed and many remain unapparent.

The occurrence of LCMV infection in persons from homes where mice have been proved to be carriers of the virus is well known.⁷ Researchers have suggested that small, persistent zoonotic foci of infection exist, on the basis of the known natural history of the disease in mice and the circumscribed range of activity of mice. The percentage of infected house mice apparently varies in different communities, and it

has been recorded at 21.5% in Washington, DC,^{5,8} and at 4% in Boston and New York.^{41,76} However, because infected mouse colonies are dispersed unevenly, the proportion of infected animals in a given infected colony can be high, up to 95%.^{32,35}

Many human cases have been reported in the context of occupational exposure to rodent colonies.^{7,16,18,19,29,31,37–39,46,51,72} Outbreaks and isolated cases of LCMV infections were reported in laboratory personnel having contact with hamsters, not mice.^{16,22,47,48} Recently a case acquired through occupational exposure presented initially as an influenza-like syndrome, complicated by pericarditis and meningoencephalitis.³

A study by real-time polymerase chain reaction (RT-PCR) assay of 130 samples of cerebrospinal fluid (CSF) from patients with acute aseptic meningitis in Switzerland showed no cases of acute infection with LCMV.²⁶ This suggests that LCMV infections are extremely rare in hospitalized patients. Until 2005, no case of person-to-person transmission had been documented, and the general consensus was that LCMV could infect humans only after direct or indirect contact with an infected rodent. The more recent evidence that LCMV can be transmitted through organ donation should lead physicians to evoke LCMV as a possible cause of infection in the absence of established close contact with mice or hamsters.^{20,21,34} In a report of LCMV infection developing after organ transplantation, the fatality rate was much higher (seven deaths in eight cases) than previously noted, perhaps a reflection of the immunosuppressive regimens required by these transplant recipients.³⁴ Another, similar episode occurred in Australia, where three patients died after receiving an organ transplant from the same donor. Next-generation sequencing provided clues about possible involvement of an arenavirus related to LCMV.^{45,61}

On April 15, 2008, an organ procurement organization notified the Centers for Disease Control and Prevention (CDC) of severe illness in two kidney transplant recipients from a common donor; at the time of notification, one of the recipients had died. Samples from the donor and both recipients were tested at the CDC; on April 22, test results revealed evidence of acute LCMV infection in the donor and both recipients. This report summarizes the results of the subsequent public health investigation.^{20,21}

Serologic studies conducted in healthy populations of large cities by either immunofluorescence assay (IFA) or enzyme-linked immunosorbent assay (ELISA) found immunoglobulin G (IgG) antibody prevalence varying between 0.3% and 4.7%: 0.3% in Marseille, France²⁷; 1.7% in Spain by IFA⁴⁹; 3.3% in Argentina⁶²; and 4.7% in Baltimore.²⁵ A study conducted in a region where murine typhus is endemic in Croatia reported an unexpectedly high prevalence, 36%, through IFA.³⁰

Serologic evidence of four acute LCMV infections was retrospectively reported in Spain in serum and CSF samples from 341 patients.²⁸

CLINICAL MANIFESTATIONS

In most cases, LCMV infection is minimally symptomatic or asymptomatic and consists of an influenza-like illness with fever, headache, myalgia, fatigue, and general malaise. These symptoms are self-limited and resolve after a few days. These mild illnesses, which usually do not motivate patients to see a physician, most likely represent most LCMV infections, but the exact proportion is unknown. Historical articles reported that respiratory symptoms occur in LCMV infections. In a certain (but unknown) proportion of cases, a second phase is observed during which neurologic manifestations, such as meningitis, encephalitis, or even acquired hydrocephalus, can be recorded.

In 1942, Farmer and Janeway³³ proposed the following classification of LCM into four clinical categories:

1. *Inapparent and subclinical infections*: Immunologic studies suggested that these forms are quite common: 11% of 2000 sera tested contained neutralizing antibodies against LCMV.⁹
2. *Nonmeningeal form, non-central nervous system (CNS) infection, systemic infection, influenza-like infection*: This form consists of two stages: systemic illness, then convalescence. The incidence probably is underestimated because of the lack of laboratory documentation and the absence of specific or suggestive signs. Only vague assumptions can be made concerning the number of underdiagnosed cases. The diagnosis of LCMV usually is not suspected unless attention is

directed to signs and symptoms suggestive of meningoencephalitis, although researchers have shown that generalized systemic infection may occur without any evidence of involvement of the CNS.⁶⁷ How often the disease manifests in this form or how often apparently asymptomatic infection occurs is not known. The demonstration of neutralizing antibodies in the blood of as many as 10% of the adult population suggests that infection with LCMV may occur more frequently than is suspected.⁷⁴

3. *Lymphocytic choriomeningitis, meningeal form*: This form usually consists of three stages: systemic illness, meningitis (possibly delayed up to 2–3 weeks), and convalescence.¹⁰ A striking example was recently reported: a 37-year old woman was admitted for meningitis 3 weeks after being bitten (and probably infected through this pathway) by a mouse at home.⁷³
4. *Lymphocytic choriomeningitis, encephalomyelitic form*: This form has three stages: systemic illness, encephalitis (possibly delayed), and convalescence. A recent case perfectly illustrates this form: a 15-year old girl was admitted to the emergency department for fever, myalgia, headache, and photophobia, and was released after a negative initial investigation; 1 week later, she was admitted again with neuroinvasive febrile manifestations.⁶⁸

Other CNS manifestations such as transverse myelitis, Guillain-Barré-type syndrome, and transient or permanent acquired hydrocephalus can be associated with LCMV infection.^{12,13} LCMV-associated acquired hydrocephalus has been described only five times since the virus was discovered.^{11,23,43,70} In all cases, the clinical picture was severe and patients required ventriculostomy.

A fifth category (congenital LCMV) should be added to the previous classification, corresponding to fetal consequences of LCMV infection during pregnancy. LCMV is a fetal teratogen. It can cause hydrocephalus, microcephaly or macrocephaly, intracranial calcifications, chorioretinitis, and nonimmune hydrops. More than 50 cases of congenital LCMV infection have been documented since 1955, with more than two thirds of these cases diagnosed since 1993. Chorioretinitis and hydrocephalus are the predominant characteristics among children diagnosed with congenital LCMV infection.⁴⁰ LCMV was isolated for the first time in the CSF of a congenitally infected infant, who had congenital hydrocephalus caused by LCMV infection with severe neurologic sequelae, including, in addition to hydrocephalus, chorioretinitis, blindness, and developmental delay.⁶⁵ The differential diagnosis of congenital LCMV infection includes toxoplasmosis, rubella, cytomegalovirus infection, herpes simplex, enteroviral infection, human parvovirus B19 infection, and syphilis.^{13,14,56,75}

Last, immunosuppressed patients, such as organ transplant recipients, can develop fatal hemorrhagic fever-like disease. Several occurrences of transmission of LCMV via organ transplantation have been documented recently.^{20,21,34} Of 11 recipients described in those clusters, 10 died of multisystem organ failure, with LCMV-associated hepatitis as a prominent feature. The surviving patient was treated with ribavirin (an antiviral agent with in vitro activity against LCMV) and reduction of immunosuppressive therapy.^{20,21} During 2002–13, the US CDC investigated several clusters of LCMV cases in patients who had received solid organ transplantation in the preceding weeks.^{4,12,14,15,59} Such events indicate that diagnosis of LCMV in the donor was undetected because of the lack of obvious manifestations and that enforcing measures for preventing similar cases is likely to be challenging.¹⁵

DIAGNOSIS

As in other viral diseases, direct diagnosis can be established by virus isolation using cell culture; Vero and L929 cells have proved effective for LCMV isolation, but other mammalian cells also can be used. Usually, either no effect or a mild cytopathic effect is noted. Routine clinical laboratories, however, may not offer isolation of LCMV in culture. Several molecular techniques using PCR technology have been described.^{17,24,32,54,60} An RT-PCR assay has recently been described.^{26,52} The main problem with all these techniques is that the genetic diversity of LCMV is poorly understood and clinical laboratories may not offer PCR assays for LCMV detection. Sequence data acquired from newer LCMV strains indicate that the genetic heterogeneity could be greater

than 20% between two strains.³² Therefore, a diagnostic assay able to amplify recognized LCMV strains may provide false-negative results with a new, uncharacterized strain. Further genetic analysis of newly discovered strains therefore will be key to developing better diagnostic tools in the future.

Several serologic techniques have been described for establishing the diagnosis of LCMV infection in patients. Among these techniques, the one that was used commonly in the past, complement fixation assay, has been demonstrated to have poor sensitivity.⁴⁷ IFA and ELISA techniques are equivalent in terms of specificity and sensitivity, although home-made ELISA may display higher sensitivity.⁴² However, because of broad cross reactivity among members of the genus *Arenavirus*, confirmation should rely on neutralization assays to discriminate between LCMV and other arenaviruses.

Serologic study can be performed with serum or CSF samples. As in other viral diseases, a fourfold difference in titers indicates a recent infection. In a single sample, detection of specific IgM suggests a recent infection. Molecular detection of LCMV genomic RNA, as well as virus isolation, can be performed from CSF during CNS manifestations and possibly from serum or plasma.

TREATMENT

No treatment exists for LCMV infection. Ribavirin has been shown to be efficient for Lassa fever,⁵³ a viral hemorrhagic fever caused by another arenavirus related to LCMV. Ribavirin was used once in a kidney transplant recipient whose immunosuppressive medications were discontinued and who received intravenous immunoglobulin when the diagnosis was established; the issue was favorable, with complete recovery.^{20,21} T-705 (favipiravir) was shown to interfere with LCMV minigenome transcription and/or replication.⁵⁵ Interestingly, this molecule is FDA approved for influenza virus infection treatment, has been recently used in clinical trials in humans during the West African Ebola virus outbreak, and has been successfully tested against a large variety of RNA viruses severely affecting humans such as Lassa virus, CCHFV, and SFTSV.^{50,58,66,69}

CONCLUSION

Since 2000, several reports have shown that LCMV has not disappeared and that it still can cause severe or fatal cases. Renewed attention was drawn to LCMV after seven recipients of solid-organ transplants died of LCMV infection.³⁴ Historically, this virus was a major cause of aseptic meningitis in the United States; LCMV ranked first during the World War II era and second during the 1947 to 1952 period.² At that time, other major causes were mumps, herpes simplex virus, and leptospirosis. The focus on LCMV declined over the intervening decades, even though the rate of unrecognized causes of CNS infections still remains high, at more than 50%.³⁶ The reason for the diminishing interest in LCMV is not clear, but it may be related to the historical prevalence of the disease in rural rather than urban populations of developed countries. However, the growing proportion of urban people living below the poverty level may lead to conditions compatible with contact with mice and, therefore, may boost the incidence of rodent-associated diseases.

In addition, the capacity to diagnose LCMV has declined dramatically since the 1980s. Hence, the decreasing number of reported cases may reflect the decrease in clinical interest and the lack of diagnostic tests, rather than a genuine modification of the epidemiology of the disease. Standard techniques, such as IFA or virus isolation, have been virtually abandoned in clinical microbiology laboratories. In Europe, the situation has been critical since 2000; barely a handful of laboratories are capable of performing recognized serologic or molecular diagnostic tests. LCMV infection still exists, and cases are reported when physicians include LCMV in the differential diagnosis and when appropriate diagnostic tests are conducted. Efforts are essential to determine the epidemiologic landscape of the disease and to implement etiologic investigations of neonates with congenital malformations who have CNS infections. The combination of poor diagnostic testing capacity and a lack of awareness of the virus among physicians may contribute directly to an underestimation of the current role of LCMV in medicine.

Arenaviral Hemorrhagic Fevers

186

Remi N. Charrel • Priya R. Soni • James D. Cherry

The Arenaviridae family of viruses consists of 38 distinct viral species, some of which cause disease in humans characterized by hemorrhagic fever syndromes. The majority of these viruses are associated with rodent-transmitted disease to humans and in one case, transmission by phyllostomid bats to humans. Arenaviruses have been classified into one of two groups based on the virus's ability to infect rodents in different geographic areas—Old World (Eastern Hemisphere) versus New World (Western Hemisphere). The New World Arenaviruses are further divided into three distinct lineages. In 1933, the original arenavirus, lymphocytic choriomeningitis virus (LCMV), was isolated by chance when a researcher was studying the St. Louis encephalitis epidemic.¹⁴⁹ Although the etiology of the outbreak was later identified as St. Louis encephalitis virus, LCMV was found to be a cause of aseptic meningitis. By the early 1950s, several other similar viruses were isolated and discovered and added to the family. Since the late 1950s it has been thought that a new Arenavirus species was discovered about every one to three years. (Lymphocytic choriomeningitis virus is discussed in Chapter 185.)

HISTORY

In the 1950s, a new disease emerged in the Buenos Aires province of Argentina, a rich farming region. The causative agent of the Argentine hemorrhagic fever (AHF), named Junín virus, was isolated in 1958.¹¹³ Junín virus is hosted by rodents widely distributed in the region, and human infection occurs through contact with infected excreta, usually by a respiratory pathway. AHF is a severe disease that is fatal in approximately 20% of cases in the absence of specific treatment. Intensive deforestation and extensive agricultural practices in this region have

increased considerably the number of contacts between humans and rodents and thereby fueled the emergence of severe annual outbreaks. Cases were expanding progressively into north-central Argentina until they finally were controlled by the availability of a live attenuated vaccine (Candid #1) developed in the early 1980s, which is licensed for use for endemic areas in Argentina.² Junín virus is estimated to have caused approximately 30,000 cases of symptomatic disease since its discovery.

Bolivian hemorrhagic fever (BHF) was described first in 1959 in the El Beni department of eastern Bolivia. The causative agent, named Machupo virus, was isolated in 1963 and was found to be antigenically and genetically distinct from but related to Junín virus.⁷⁵ Machupo virus was responsible for large outbreaks with high incidence (up to 21% of the population) and a case-fatality rate of approximately 20% during the 1960s. Effective rodent-control efforts interrupted these epidemics, and after the mid-1970s, no cases of BHF were reported. After 20 years of silence, however, 19 additional cases were reported in the same region from 1993 to 1999.⁸

An outbreak of severe hemorrhagic fever began in the state of Portuguesa, located in the central plains of Venezuela, in 1989. Initially thought to be dengue hemorrhagic fever, the causative agent was isolated in 1990, identified as a new arenavirus species, and named Guanarito after the municipality where the first epidemic occurred.¹²⁵ Venezuelan hemorrhagic fever (VHF) presents a seasonal occurrence clearly related to intense agricultural activity and to human contact with the soil and the rodents hosting Guanarito virus.

Little is known about Sabiá virus, which was responsible for one fatal case of hemorrhagic fever near São Paulo (Brazil) in 1994.⁸³ Subsequently, two other cases were reported in laboratory workers. The epidemiology and the natural reservoir of Sabiá virus remain unknown.

In 1999 and 2000, three fatal cases of illness were reported in female patients aged 14, 30, and 52 years; two resided in northern California and one in southern California.^{24,25} These cases were associated with Whitewater Arroyo virus infections, a recently described arenavirus indigenous to the southwestern United States and hosted by *Neotoma* rodents.⁵⁴

In the Old World, Lassa fever was described initially in Nigeria in 1969 when two missionary nurses died in the town of Lassa, and the causative virus was identified during that same year.¹⁷ The disease occurs also in Sierra Leone, Guinea, and Liberia and several neighboring countries in the West African region, including Mali and Ghana.

ETIOLOGIC AGENTS

Arenaviruses are enveloped single-stranded negative sense RNA viruses with a genome consisting of two RNA segments, designated large (L) and small (S). The L genomic segment (~7.2 kb) encodes the viral RNA-dependent RNA polymerase and a zinc-binding protein (matrix protein Z). The S genomic segment (~3.5 kb) encodes the nucleocapsid protein (N) and glycoprotein precursor (GPC; secondarily cleaved into the G1 and G2 envelope glycoproteins) in nonoverlapping open reading frames of opposite polarities.¹³² Nucleocapsid antigens are shared by

most arenaviruses, and quantitative relationships show a basic split between viruses of Africa and viruses of the Western Hemisphere. Individual viruses are distinguished immunologically by neutralization test, which depends on the specificity of epitopes contained in the envelope glycoproteins.¹¹⁵

At present, 38 arenaviruses are recognized (Table 186.1). They have been classified according to their immunologic characteristics. Two groups are recognized (Fig. 186.1): the Tacaribe serocomplex, including the New World viruses; and the Lassa-lymphocytic choriomeningitis (LCM) serocomplex, including the ubiquitous LCM virus and all recognized Old World viruses. Genetic studies are congruent with serologic analyses.⁴⁰ They also indicate that the 38 arenaviruses represent four phylogenetic lineages. The Old World (Lassa-LCM serocomplex) lineage comprises 14 viruses (LCM, Lassa, Mopeia, Mobala, Ippy, Merino Walk, Menekre, Gbagroube, Morogoro, Kodoko, Lujo, Lemniscornys, Mus minutoides, and Luna). The three New World (Tacaribe serocomplex) lineages are designated A, B, and C (see Fig. 186.1). The lineage A includes eight North American viruses (Whitewater Arroyo, Tamiami, Bear Canyon, Real de Catorce, Tonto Creek, Skinner Tank, Big Brushy Tank, and Catarina) and five South American viruses (Piritral, Pichindé, Flexal, Paraná, and Allpahuayo). The lineage B includes nine South American viruses (Sabiá, Junín, Machupo, Guanarito, Amapari, Tacaribe, Cupixi, Ocozocoautla de

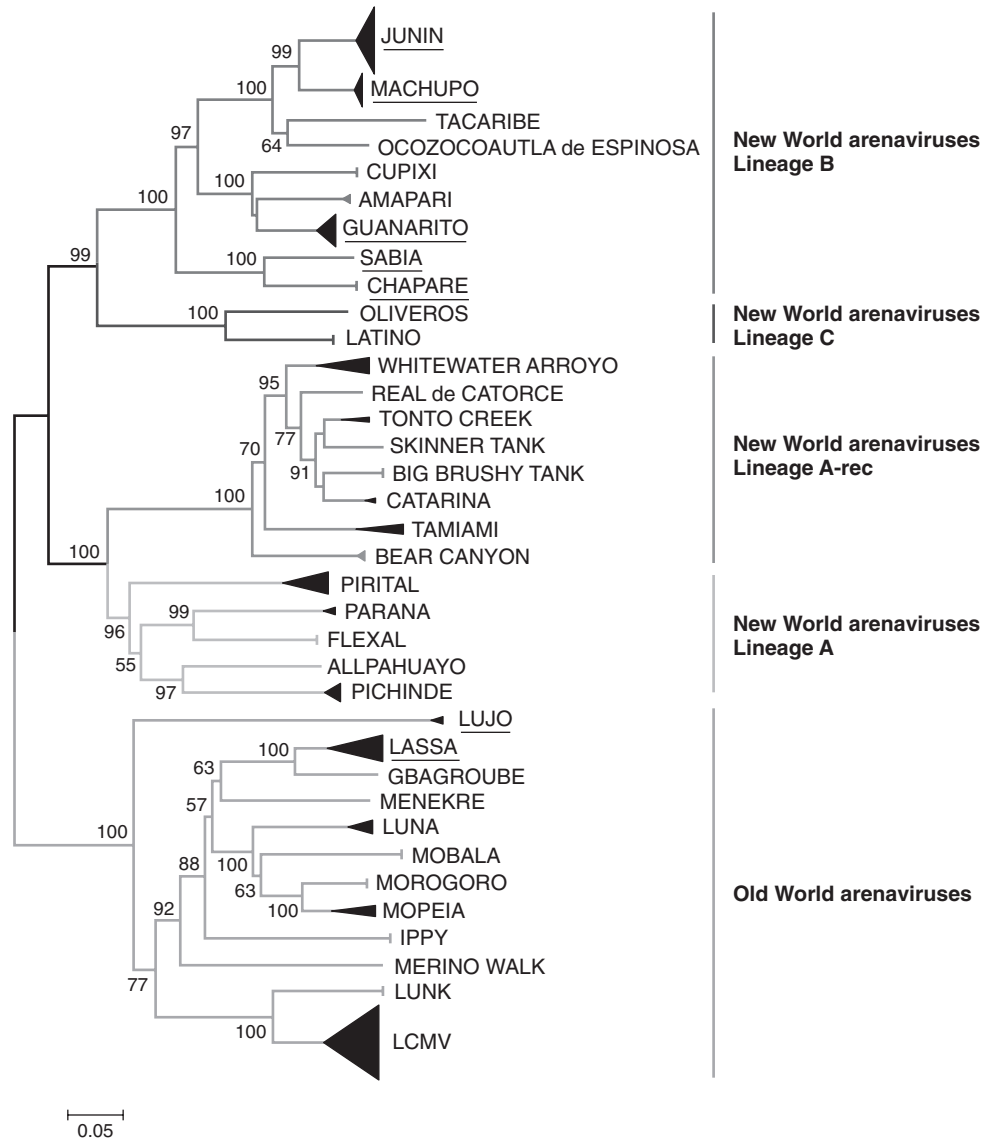

FIG. 186.1 Phylogeny of arenaviruses based on the analysis of complete sequences of the NP gene. A, B, and C show the three evolutionary lineages of New World arenaviruses. A-Rec denotes the recombinant lineage including the North American viruses. Bootstrap values above 75% are indicated and correspond to 500 replications.

Espinoza, and Chapare). The lineage C comprises three South American viruses (Oliveros, Latino, and Pampa). Phylogenies reconstructed from each of the four genes independently demonstrated that the eight North American arenaviruses possess a chimeric genome, with the glycoprotein gene inherited from a clade B ancestor and the nucleoprotein gene inherited from a clade A ancestor; this mechanism could not be identified within the large genomic segment, with both polymerase and matrix genes more closely related to those of clade A viruses.²⁷⁻²⁹

Lassa and Lujo viruses are the only Old World arenaviruses that cause human hemorrhagic fever, whereas five New World members of the lineage B (Junín, Machupo, Guanarito, Sabiá, and Chapare) have been associated with hemorrhagic fever in South America. Although Whitewater Arroyo virus has been associated with three fatal human cases in North America in 1999-2000, other cases of infection have not been reported since.

During the past decade, novel arenaviruses were discovered in snakes (in the families Boidae and Pythonidae, i.e., boas and pythons), in which they cause an illness called inclusion body disease that is characterized by behavioral abnormalities, wasting, and secondary infections.^{121,134} The three new viruses were provisionally named California Academy of Sciences virus (CASV), Golden Gate virus (GGV), and Collierville

virus (CVV). These viruses have a typical arenavirus genome organization but are highly divergent, belonging to a lineage separate from that of the Old and New World arenaviruses. Interestingly, these viruses encode envelope glycoproteins that are more similar to those of filoviruses than to those of other arenaviruses.¹³⁴

Specific rodents (usually one or two closely related species) are the principal hosts of the arenaviruses for which natural host relationships have been characterized (Table 186.2); the only exception is Tacaribe virus, which was first isolated during a rabies surveillance survey from bats and mosquitoes in the late 1950s.¹²⁷

The consensus is that the diversity of arenaviruses is the result of a long-term, shared evolutionary relationship (termed co-evolution or co-speciation) between the virus members of the family Arenaviridae and the rodents of the family Muridae.^{11,12} Chronic infections of the host appear to be crucial to the long-term persistence of arenaviruses in nature. The infection in rodents is accompanied by a chronic viremia or viruria. Because of this specific association, the geographic area where each arenaviral disease is diagnosed is limited by the geographic distribution of the corresponding rodent host.

The rodent host of Junín virus is *Calomys musculus*, a small field rodent. Since it was first isolated in 1959, the endemic area has expanded

TABLE 186.2 Epidemiologic Features of Arenaviral Hemorrhagic Fevers

Fever	Virus	Case, Season, Place, Pattern	Annual Incidence	Geographic Distribution	Ecology	Rodent Reservoir	Comment
Argentine hemorrhagic fever	Junín	Males; corn harvest; March-June	20-200	North-central Argentina	Temperate pampa	<i>Calomys musculus</i>	3- to 4-year rodent-disease cycle
Bolivian hemorrhagic fever	Machupo	All ages, both sexes; villages; February-July	<10	Northeast Bolivia	Tropical savanna	<i>Calomys callosus</i>	Rodent control successful
Venezuelan hemorrhagic fever	Guanarito	All ages, both sexes equally; house, gardens; no seasonality	0-100	Central Venezuela	Tropical mixed savanna	<i>Zygodontomys brevicauda</i> <i>Sigmodon alstoni</i>	Recently described
Brazilian hemorrhagic fever	Sabiá			Brazil		Unknown

	Lujo			South Africa		Unknown	Recently described

from a region of 16,000 km² in the north of Buenos Aires Province to a region that is now 150,000 km² (reaching north of Buenos Aires, south of Santa Fé, southeast of Córdoba, and northeast of La Pampa provinces). The human population at risk now is estimated to be almost 5 million.^{42,44} AHF caused by Junín virus is typically a seasonal disease, with a peak frequency in the corn harvesting season from March to June; during this period, 75% of the infected people are male agricultural workers who are contaminated by inhalation of infected aerosols produced from rodent excreta or from rodents caught in mechanical harvesters.⁹⁰ Since 1958, cases have been recorded annually, with a variation ranging from several hundred to 3500. The mortality rate for patients with confirmed AHF was 14% to 17% before immune plasma was used routinely.⁹¹ Evidence indicates that the number of human cases reflects the proportion of infected *C. musculus* in a particular area.¹⁰⁶ Since vaccination has been started with Candid #1 vaccine, there has been even a significant reduction in the incidence of AHF.^{15,16}

Machupo virus, the causative agent of Bolivian hemorrhagic fever (BHF), is hosted by *Calomys laucha* rodents. As for Junín virus, the dynamics of the rodent population determine the epidemiologic features in humans.¹⁰¹ By contrast to *Calomys callosus*, *C. laucha* invades houses during inundation at the rainy season; this invasion results in human cases occurring with an attack rate identical in men, women, and children. The disease has been recorded only from a sparsely populated region in northeast Bolivia, the El Beni Province. From 1962 to 1964, a series of outbreaks involved more than 1000 patients, 180 of whom died. Nosocomial transmission of Machupo virus was clearly demonstrated,¹¹⁶ although most of the recorded infections were acquired by direct contact with *C. laucha* or by aerosol contact through infected excreta.

In 1990, new cases of hemorrhagic fever were investigated in Venezuela; the culprit was found to be a new arenavirus, designated Guanarito virus after the region where the outbreak occurred.¹²⁵ Natural and experimental data suggest that two different rodent species are involved in the transmission cycle of Guanarito virus in nature: the cane rat, *Zygodontomys brevicauda*; and the cotton rat, *Sigmodon alstoni*.^{55,57,137} Since its discovery, Guanarito virus has been responsible for at least 200 cases of VHF. For unknown reasons, the number of reported human cases has dropped spontaneously since 1992, although rodent infection can still be demonstrated easily inside and even outside the original endemic zone.¹⁴⁶

In December 2003 and January 2004, a small number of hemorrhagic fever cases were reported in rural Bolivia, outside of the known Machupo hemorrhagic fever endemic zone. The patients had symptoms similar to those seen with other arenaviral hemorrhagic fever cases—acute febrile illness beginning with headache, joint and muscle pain, and

vomiting—and rapidly progressed to shock, bleeding, and death at 14 days after onset of illness. In the serum from one fatal case, a novel arenavirus was isolated and sequenced.³⁶

In California, three fatal cases in 1999–2000 were associated with Whitewater Arroyo virus, initially isolated from a wood rat (*Neotoma* spp.).^{24,25,54} The present-day geographic range of rodents of the genus *Neotoma* extends from western Canada southward to Guatemala, Honduras, and Nicaragua. Of the 20 recognized *Neotoma* spp., nine occur in the United States, and evidence of arenavirus infection has been reported for five of them. Field studies have provided strong evidence that Whitewater Arroyo virus circulates in the states of New Mexico, Utah, Texas, Oklahoma, Arizona, and Colorado.^{18,56} The abundance and habits of wood rats suggest that potential contact between *Neotoma* rodents and humans is limited. Recent data support the fact that Whitewater Arroyo virus can infect humans.¹⁰³

Lassa virus (LASV) is associated with a primary reservoir species, which is the natal multimammate mouse of the *Mastomys* genus. These mice are widely distributed in sub-Saharan Africa. However, it seems that the virus's range is restricted to West Africa. Documented cases of Lassa fever have been reported in several West African countries, such as Nigeria, Liberia, Sierra Leone, Burkina Faso, Guinea, Ivory Coast, Ghana, Senegal, Gambia, and Mali.^{19,50,52,69,98,126,138} It is important to note that in some countries, including Guinea-Bissau, Senegal, Togo, Niger and Cameroon, fewer cases of Lassa fever are reported because of their low level of health care infrastructure.¹¹⁹ Between 1985 and 1987, three of 5000 (0.06%) randomly selected persons living in six central African countries (Cameroon, Central African Republic, Chad, Congo, Equatorial Guinea, and Gabon) tested for serologic evidence of LASV infection were found to have antibody.⁶¹ In contrast, a second study conducted with individuals living in different parts of Nigeria found that 21.3% of the 1677 tested antibody positive.¹³⁸ Lassa fever is a disease of major public health importance in West Africa because it causes an estimated 5000 to 10,000 deaths and as many as 300,000 infections annually in endemic areas.⁶⁵ The first epidemic was described in 1969 in Nigeria when two missionary nurses died¹⁷ and soon was followed by several other epidemics in nearby countries. Among hospitalized patients, the mortality rate is estimated at 15% to 20%.¹⁴⁷ In hospitals located within the endemic area, 10% to 17% of admissions are caused by Lassa fever. However, serologic surveys suggest that subclinical cases occur and result in a lower overall mortality (<1%).⁹⁸ The overall incidence of Lassa fever in West Africa may be tens of thousands to hundreds of thousands annually. An important characteristic of Lassa fever is that there is a risk of secondary transmission of the virus from human to human through direct contact with blood or secretions from infected

TABLE 186.3 Laboratory Findings in Arenaviral Hemorrhagic Fevers

patients and by aerosol exposure.⁷⁷ Many nosocomial outbreaks have been described. Another characteristic of Lassa fever is that a number of cases are acquired by local residents who seek out rodents for consumption.¹³⁶ Because of the prevalence of virus transmission, Lassa fever is a prominent threat of imported hemorrhagic fever cases; such cases have been reported in England,³¹ Germany,⁶⁴ Japan,⁷⁰ the Netherlands,¹⁴³ Israel,¹²⁹ and the United States.⁷¹ A comprehensive report of imported Lassa fever recorded 24 cases occurring from 1969 to 2004, with a fatality rate of 29%.⁸⁸ Currently it is observed that the overall case-fatality rate is 1%, with overall case-fatality among patients hospitalized with severe cases up to 15%.¹⁴⁸

In fall 2008, five cases of hemorrhagic fever were reported in South Africa after air transfer of a critically ill index case from Zambia. Four of them were fatal; the fifth case received ribavirin and recovered. Next-generation sequencing from serum and tissue samples detected a novel arenavirus that was subsequently completely sequenced. Lujó virus (LUJV) was named after its geographic origin (Lusaka, Zambia, and Johannesburg, South Africa).¹⁴

PERSON-TO-PERSON TRANSMISSION

Although human-to-human transmission of BHF has been seen only rarely and then only after intimate contact, Machupo virus clearly was responsible for severe nosocomial outbreaks in which all cases were associated with a single index case who had returned from the endemic region. The only recognized hospital-based outbreak resulted in four secondary cases followed by a tertiary case acquired from a necropsy incident; all but one died. An epidemic was reported in which seven members of the same family were infected, with a fatal outcome for six.²³

Nosocomial transmission is a common feature of Lassa fever, and many nosocomial outbreaks have been described.^{48,77} However, it is apparent that this aspect of Lassa fever has been overestimated in reports based on infections in hospitals. The additional risk to hospital workers within the endemic zone is not great as judged by serosurveys, provided that basic hygiene measures are respected in hospitals in dealing with suspected cases.⁶⁸ Good barrier nursing and protection of personnel by use of gloves, gowns, and eye shields have reduced the incidence of such infection in recent years. Broader surveys of community infections have revealed Lassa fever to be an important community-acquired disease, with a wide spectrum of clinical manifestations. Because LASV has been isolated from breast milk, there is a risk to nursing children.

Concerning Lujó virus (LUJV) infection, an index patient was airlifted from Zambia to a clinic in South Africa, after infection from an unidentified source. Secondary infections were recognized in a paramedic (case 2) who attended the index case during air transfer from Zambia, in a nurse (case 3) who attended the index case in the intensive care unit in South Africa, and in a member of the hospital staff (case 4) who cleaned the room after the index case died. One case of tertiary infection was recorded in a nurse (case 5) who attended case 2 after his transfer from Zambia.¹¹⁴ The distribution of this newly described arenavirus is still not fully known.

In conclusion, the data demonstrating nosocomial and human-to-human transmission of several arenaviral diseases highlight the necessity for implementing biocontainment precautions in dealing with arenavirus-infected patients and materials. LASV is classified as a Biosafety Level 4 (BSL4) and NIAID Biodefense category A agent, because of high case-fatality rates, ability to spread quickly through secondary human-to-human transmission, and the potential for aerosolized release.

It is important to note that agricultural workers and those in rural communities are at highest risk. It is thought that transmission to humans in these settings results from the virus being carried on dust particles or by direct ingestion of contaminated food products. Overall the majority of human infections occur primarily by aerosol or close contact with rodent excreta or contamination of food or through skin abrasions.¹⁰⁶

CLINICAL MANIFESTATIONS

The clinical pictures of the South American arenaviral hemorrhagic fevers are almost identical, regardless of the virus responsible for the disease. The incubation period usually is 10 to 14 days, with an extreme incubation time extending from 5 to 21 days. Infection secondary to high-load inoculum may result in the reduction of the incubation period to 2 days. The onset is gradual with fever and malaise, secondarily joined by myalgia, back pain, headache, and dizziness. Hyperesthesia of the skin is a common manifestation. Petechiae of the skin and hemorrhages from the gums, vagina, and gastrointestinal tract beginning about the fourth day of illness herald the advent of hypovolemic clinical shock. Blood loss usually is minor, so the hematocrit generally increases as capillary leak syndrome, a hallmark of the disease, becomes more severe (Table 186.3). Bleeding and prothrombin time may be prolonged, and reductions of factors II and VII of the coagulation cascade have been noted. Renal function is generally preserved until shock occurs, but urinary protein concentration may be high. Neurologic manifestations are prominent and include intention tremor of the hands, and inability to swallow or to speak clearly may develop. These symptoms can progress to grand mal convulsions, coma, and death in the absence of significant capillary leak or hemorrhagic signs. Death usually occurs 7 to 12 days after onset of disease. Those who survive generally recover completely without permanent sequelae, although transient loss of scalp hair and Beau lines in digital nails are a common consequence of the high and sustained fever.

Symptoms that appear to be more specifically associated with one or another of the viruses have been reported.¹⁴² Although the frequency of clinical and laboratory findings is identical for Junín and Machupo virus infections, clear differences exist with Guanarito virus infections. Pharyngitis, vomiting, and diarrhea are observed more frequently with Guanarito virus; in contrast, petechiae, erythema, facial edema, hyperesthesia of the skin, and shock are observed more frequently in the case of Junín or Machupo infection. There seems to be little difference, if any, between clinical manifestations caused by these three viruses and the recently isolated Chapare virus; the patient, a 22-year-old man, had lived for the last 4 years in the same region. He was a tailor and also a farmer. He had no history of travel and no contact with any case with compatible illness for at least 4 weeks before his disease onset. In addition, no members of the case household or other close contacts were affected. His clinical course included fever, headache, arthralgia, myalgia, and vomiting, with subsequent deterioration and multiple hemorrhagic signs and death 14 days after onset.³⁶

Fatal outcome of Junín virus infection is observed more frequently in pregnant women in the third trimester, and a high fetal mortality is associated with Junín and Machupo virus infections.^{15,16,38,73}

The symptoms of Argentine hemorrhagic fever (Junín virus), Bolivian hemorrhagic fever (Machupo virus), and Venezuelan hemorrhagic fever (Guanarito virus) are distinct from those of Lassa fever in that hepatitis rarely occurs, whereas it occurs frequently in severe Lassa fever. Overall, hemorrhaging, neurological signs and symptoms, leukopenia, and

thrombocytopenia are more common in the three Latin American hemorrhagic fevers in comparison to Lassa fever. The increased urinary protein and increased hemoconcentration seen in these three viral infections are associated with a higher rate of mortality.¹¹⁸ In severe episodes, patients with these viral infections develop hemorrhagic fever, leukopenia, thrombocytopenia, leukopenia, hematuria, tremors, pulmonary edema, respiratory distress, coma, and shock.¹³¹

The patients infected with Whitewater Arroyo virus were healthy before acquiring the virus infection. In one case, the patient probably acquired the virus by aerosol pathway while cleaning rodent droppings at home. In all cases, no history of travel outside California was found during the 4 weeks preceding the illness. The onset was characterized by nonspecific febrile symptoms including fever, headache, and myalgia. All patients presented with acute respiratory distress syndrome, and two developed liver failure and hemorrhagic manifestations. Death occurred within 8 weeks after the onset.^{24,25}

Concerning Lassa fever, the clinical description is based on signs observed in hospitalized patients.^{51,76,115} After an incubation period that ranges from 7 to 14 days, patients suffer an insidious onset characterized by progressive fever, malaise, and generalized myalgia. Retrosternal pain frequently is associated with this phase. In these earlier stages, Lassa fever is often misdiagnosed as influenza, typhoid, or malaria. The symptoms, however, increase in severity during the following week and are accompanied by nausea, vomiting, diarrhea, chest pain, abdominal pain, headache, sore throat, cough, and dizziness. Patients complain of sore throat, pharyngeal inflammation, and chest pain. As the disease progresses, vomiting, diarrhea, hemorrhagic manifestations, encephalopathy, and evidence of vascular permeability may be noted. During the second week, recovery may begin or the disease progressively worsens until harbingers of a fatal outcome are evident: severe edema, mucosal hemorrhages, pulmonary involvement, encephalopathy (with seizures and coma), or shock; at this stage, pleural and pericardial effusions and ascites are not rare findings. Liver involvement is frequent, but icterus is not usual. Death occurs in 15% to 20% of the hospitalized patients, usually in the second or third week of the course, and is associated with sudden cardiovascular collapse caused by hepatic, pulmonary, and myocardial damage. Few patients develop severe central nervous system (CNS) signs, and disturbances in consciousness and convulsions are markers of a poor prognosis. Deafness is an important sequela of Lassa fever; it may be unilateral or bilateral and is a consequence of eighth cranial nerve dysfunction. It can be observed in as many as 30% of patients.

Clinical disease among children generally is similar to that in adults. Systematic data are available only for Lassa fever patients.^{105,147} Fever, vomiting, diarrhea, and cough are common presenting symptoms. Pulmonary signs, including rales and pleural effusion, are seen more commonly in children than in adults. Among very young children, especially those infected antepartum, an unusual condition called swollen baby syndrome has been described. It is marked by abdominal distention, widespread edema, and spontaneous bleeding. In a small review of cases from Liberia, it seemed that the absence of this clinical presentation was a good prognostic indicator in children.¹⁰⁵

LASV replicates at a very high level in the placenta of pregnant women, which might account for the high mortality rate observed in these patients. The risk for death in pregnant women is estimated to vary from 7% in the first two trimesters to 30% in the third trimester, compared with the 13% mortality in nonpregnant women. A high fetal mortality rate varying from 92% in early pregnancy to 75% in the last trimester has been observed.^{102,104,120}

Although few cases of LUJV infection have been reported, it appears that the clinical manifestations are not drastically different from those observed with other arenaviruses. The putative incubation period ranged from 7 to 13 days, and the period of illness varied from 10 to 13 days. All patients presented with nonspecific febrile illness with headache and myalgia. The severity increased for 7 days with diarrhea and pharyngitis. A morbilliform rash was observed on the face and trunk of white patients but was lacking in African patients. Transient subjective improvement after approximately 1 week of illness was reported; afterward, the patients endured a rapid deterioration with respiratory distress, neurologic signs, and circulatory collapse, the terminal features

in patients who died. Bleeding was not a prominent feature. However, petechial rash, gingival bleeding, and oozing of blood from venipuncture sites were observed. Chest pain was a prominent symptom for two patients. All patients had thrombocytopenia on admission to the hospital (platelet count range, 20 to 104 × 10⁹ cells/L). Three patients had leukocyte counts in the normal range, and two had leukopenia on admission, whereas leukocytosis developed in four patients during the illness. The highest aspartate transaminase values recorded in the patients who died ranged from 549 to 2486 U/L, compared with 240 U/L in the survivor who was treated with ribavirin.¹¹⁴

Very little is known about the health consequences of infection with the other arenaviruses. Aerosol infections are common in those who work in laboratories where arenaviruses are manipulated. Pichindé virus has resulted in several seroconversions without any notable clinical significance.¹³ Flexal virus has resulted in two severe laboratory infections and should be regarded as potentially dangerous (E. Pinheiro, personal communication). Tacaribe virus has resulted in a single case of febrile disease with mild CNS symptoms (J. Casals, personal communication).

PATHOGENESIS AND PATHOLOGY

Human and nonhuman primate infection initially involves virus replication at the site of infection, usually in the lung after infected aerosol deposition in the terminal respiratory bronchioles. Replication occurs in the hilar lymph nodes, and despite interstitial infiltration, pneumonic foci usually are not observed. Regardless of the route of infection, the macrophage is a site of important viral replication. With the exception of the hepatitis peculiar to Lassa fever, the pathologic process of arenaviral hemorrhagic fever is notable for the general lack of parenchymal histologic damage. Edema of tissues and focal hemorrhages in mucosal surfaces and fascia of many organs are common events. Rarely, blood clots are found that are large enough to be of clinical significance. Thus, the crucial and life-threatening lesion in these diseases appears to be the capillary leak. How capillary leak, in which plasma protein and fluid escape the circulation at a much higher rate than erythrocytes do, occurs is not clear.¹¹⁵

Hemorrhages are common findings with New World arenaviruses causing hemorrhagic fever. The prominent thrombocytopenia seen has a central origin possibly linked to high levels of interferon observed in these patients.⁸² Minor foci of necrosis with acidophilic inclusions (Councilman bodies) have been reported in patients with BHF,³⁰ and erythroid hypoplasia of bone marrow as well as lymphoid depletion of nodes and spleen may be present. Histologic evidence of disseminated intravascular coagulation generally is absent. Inflammatory lesions of the CNS are lacking. Mild inflammation of the myocardium has been noted in patients with BHF. The Argentine and Bolivian fevers may be marked by encephalopathy. Virus is not recovered from cerebrospinal fluid of patients presenting such CNS symptoms with the South American agents. Macrophages and lymphocytes or their precursors are targets for infection, and an activation of the complex cytokine cascade occurs, which can cause endothelial cells of small capillaries to lose the tight continuity that keeps proteins and red cells inside the circulation. As part of this cascade, levels of interferon are elevated. Analysis of the serum levels of hematopoietic growth factors suggested a link between granulocyte colony-stimulating factor serum levels and the severity of the illness in humans.⁹³ Similarly, interleukin-8 is thought to play an essential role in neutrophil activation.⁹⁴ Specific antibodies may not appear until 3 to 4 weeks after the onset of the disease. However, New World arenaviruses that cause hemorrhagic fever are neutralized more readily, and immune serum-based therapy has been successful in humans. Preliminary studies of VHF suggest that this disease resembles those caused by other South American relatives.^{35,125} Genetic analysis of Junin and Guanarito virus sequences amplified from human cases in Argentina and Venezuela, respectively, failed to identify any genetic marker correlating with human pathogenicity or with the severity of clinical forms.^{58,146}

Although only three cases have been reported to date, Whitewater Arroyo virus infection seems to be associated with profound lymphopenia and thrombocytopenia.^{24,25} To date, no studies have been performed to

investigate the pathogenesis of Whitewater Arroyo virus infection. An interesting note is that Whitewater Arroyo virus belongs to lineage A (based on genetic analysis performed in the nucleocapsid gene), in which no other members have been recognized so far as human pathogens. However, the small genomic segment of Whitewater Arroyo virus has been shown to have a dual origin: the gene encoding the nucleocapsid is inherited from an ancestor belonging to lineage A, whereas the glycoprotein precursor gene is inherited from an ancestor belonging to lineage B.²⁷ Further investigations are needed to clarify whether the lineage B–inherited GPC gene is responsible for the putative human pathogenicity of Whitewater Arroyo virus.

The model for LASV pathogenesis has been carefully studied. Macrophages and dendritic cells represent the targets of early infection in humans, as in many of the other virus infections as mentioned earlier. In LASV, instead of the virus then being recognized and presented as a foreign antigen, the virus establishes an infection that evades the immune system and therefore does not stimulate T cells. This contributes to immunosuppression. It is also known that LASV infection in macrophages does not result in the production of excessive cytokines, but the cells release high amounts of infectious virus. In the hepatocytes, the infection leads to elevation in transaminases and hepatocellular necrosis. The virus is also known to replicate heavily in the adrenal cortex. The high viral load there may contribute to alterations in mineralocorticoids leading to fluid imbalance. LASV is also known to infect vascular endothelial cells without causing the overt cytopathology seen in other viruses.¹⁰⁶

The hepatitis of Lassa fever is represented by different stages successively characterized by hepatocellular injury, necrosis, and regeneration, any of which may be present at death. In no instance is the degree of hepatic damage sufficient to be responsible for hepatic failure; consequently, the hepatitis of Lassa fever is not the primary cause of death.^{74,97} For the cases characterized by encephalopathy, correlation could not be established with the presence of LASV in the cerebrospinal fluid or with virus antibodies in cerebrospinal fluid or serum; no evidence shows that the encephalopathy observed in Lassa fever is the consequence of either direct cytopathic or immune-mediated mechanisms.³² Direct damage to circulating leukocytes is not demonstrated, and profound thrombocytopenia does not occur.

In human cases of Lassa fever, no correlation exists between antibody levels and outcome of the disease.⁴⁶ More than one third of patients have antibodies to the nucleocapsid of the virus on admission to the hospital. These antibodies do not neutralize the virus, which is found in blood in concentrations much higher in severe infection than in any of the other arenaviral diseases. During convalescence, viral neutralizing antibodies evolve for months and rarely reach levels even one tenth of those that develop after infection with the other viruses in this group. Recovery from LASV infection usually precedes the appearance of neutralizing antibodies, indicating that cellular immunity plays a primary role in viral clearance. Thus, it seems reasonable to speculate that compromise of cell-mediated immunity is responsible for uncontrolled virus replication and functional capillary collapse. Primates challenged with LASV or naturally infected patients who recovered from acute Lassa fever usually do not exhibit a measurable neutralizing antibody response. Individuals who are seropositive exhibit a strong memory CD4⁺ T-cell response against the nucleocapsid protein of LASV.¹³⁵ Experiments based on inactivated vaccines have shown that in spite of the resulting synthesis of high titers of antibodies, vaccination did not prevent virus replication and death in nonhuman primates.⁴⁶ It therefore seems obvious that control of human Lassa fever involves mostly T cells through a Th1-type immune response. In addition, immune response requires epitopes located on both GP1 and GP2 glycoproteins to protect efficiently primates challenged with Lassa virus.⁴⁶

Furthermore, α -dystroglycan has been identified as a major receptor for LCM and Lassa viruses. In New World arenaviruses, only clade C viruses (Oliveros and Latino) use α -dystroglycan as a major receptor, whereas clade A and clade B arenaviruses use distinct and widely expressed receptors.^{123,133} Functional receptors for South American hemorrhagic fever arenaviruses (Guanarito, Junín, and Machupo) were found on most human cell types and cells derived from nonhuman primates and rodents.¹²⁴

Last, it is important to note that several animals have provided reasonable models for the clinical disease seen in humans. Junín virus causes fatal hemorrhagic disease in guinea pigs; rhesus monkeys are good models for Lassa⁷² and Machupo virus infections; and marmosets (*Callithrix jacchus*) reproduce the pathogenesis of Junín virus. Indeed, rhesus monkeys were used to predict the effectiveness of the antiviral drug ribavirin to treat Lassa fever, and guinea pigs were instrumental in the development of an attenuated vaccine for AHF. The paired Syrian golden hamster and Pirital virus (a nonpathogenic clade A arenavirus) has been shown to be a model to mimic clinical virologic and pathologic changes observed with Lassa fever in humans.¹²⁸

DIAGNOSIS

Differential Diagnosis

Differential diagnosis of Lassa fever should include malaria, typhoid, shigellosis, dengue, and yellow fever. For South American viruses causing hemorrhagic fever, the differential diagnosis includes yellow fever, dengue hemorrhagic fever, hepatitis, leptospirosis, hemorrhagic fever with renal syndrome (caused by hantaviruses), rickettsial diseases, typhoid, sepsis with disseminated intravascular coagulation, and, in the case of CNS involvement, viral encephalitis.

For biosafety reasons, suspected cases must be reported to national laboratories having the expertise and capacity for molecular diagnostics of viral hemorrhagic fevers together with a procedure for handling and transportation of specimens. Isolation of virus must be attempted in biosafety level 4 laboratory facilities.

Predictive Value

In West Africa, the association of fever, pharyngitis, retrosternal pain, and proteinuria presented a predictive value of 81%. In the endemic area of Argentina, the constellation of asthenia and dizziness accompanied by petechiae and conjunctival congestion has been shown to be indicative for the diagnosis of AHF; the presence of leukopenia, thrombocytopenia, and proteinuria further reinforces the diagnostic suspicion based on clinical findings. The association of a platelet count of less than 100,000/mm³ and a white blood cell count of less than 2500/mm³ or less than 4000/mm³ was reported to have a sensitivity of 87% and 100%, respectively, and a specificity of 88% and 71%, respectively.⁶⁶

Direct Diagnosis

Serum or heparinized plasma should be collected during the acute febrile stages of the disease. The samples should be frozen on dry ice or in liquid nitrogen. Storage at temperatures higher than -40°C will result in the progressive loss of infectivity. Classically achieved by virus isolation, direct diagnosis now may be performed by reverse transcription polymerase chain reaction (RT-PCR) assay, more specifically through real-time RT-PCR. Isolation of the virus is achieved readily in cell culture; Vero cells are a sensitive substrate for such direct diagnosis. Because cytopathic effect is not always observed, arenavirus-infected cells are detected by an immunofluorescence test.

For South American arenaviruses causing hemorrhagic fevers, the delay for isolation on Vero cells is 1 to 5 days, much faster than animal inoculation, which requires 7 to 20 days before illness develops. Serum and throat washings collected 3 to 10 days after onset usually yield virus. Virus is isolated less frequently from urine. Specifically, Machupo virus is recovered from only 20% of acute-phase sera and even less frequently from throat washings or urine. When serum or throat samples are collected within 2 weeks of clinical onset, the level of success in isolating LASV is very high.

Currently there are no commercially available diagnostic assays for LASV, and the limitation of research laboratories in endemic areas makes laboratory diagnosis more difficult. However, when possible, viral RNA can be purified from serum, plasma, urine, throat washings, and tissues and can be used as a target for cDNA synthesis with use of a reverse transcriptase. This cDNA can be amplified by a PCR assay with consensus primers or specific primers. The amplified region finally is sequenced for diagnostic confirmation. RT-PCR–based diagnosis offers the advantages of reducing the delay of response and possessing a greater sensitivity compared with cell culture. Specifically, several protocols using conserved

primers have been used. These target the 5' region of S-RNA. These techniques have been applied successfully to Lassa fever diagnosis, and several of these methods have been validated with large numbers in field isolates of LASV strains.⁷⁸ Molecular tests based on the RT-PCR methodology are being developed increasingly for the diagnosis of arenaviral infections.⁸⁷ For Junín and Machupo virus infection specifically, this technique is the only one that is early and sensitive enough to detect low viremia encountered during the period in which immune plasma therapy can be used effectively.⁸⁵ At the time of admission to the hospital, RT-PCR detected LASV RNA in 79% of patients; for comparison, in these patients, immunofluorescence assay detected antibodies in only 21%. By the third day of admission, 100% of the patients tested positive by RT-PCR analysis, whereas only 52% tested positive by the immunofluorescence assay.³⁷ The drawbacks of molecular methods consist mostly of the need for sophisticated equipment to be fully applicable in the field conditions when an outbreak occurs. Although considerable progress has been recently made, and equipment for RNA extraction and real-time PCR is accessible more easily, the Ebola outbreak in West Africa has underlined that the situation is far from optimal.

Additional techniques for direct detection of virus in tissues are being actively developed; they include in situ nucleic acid hybridization techniques. Antigen-detection enzyme-linked immunosorbent assay (ELISA) has been a sensitive tool in a number of patients.

More recently, molecular assays taking advantage of the real-time PCR technology have been reported for the detection of the four South American arenaviruses causing VHF. Apart from assays specific for one virus, a universal clade B PCR assay proved able to detect 5 to 500 TCID₅₀ per reaction for Junín, Machupo, Guanarito, and Sabiá viruses and also for Tacaribe, Cupixi, and Amapari viruses.¹⁴⁴ These tests have application to laboratory diagnosis on human specimens but also can be used to detect arenaviruses in rodent tissues. Real-time RT-PCR assays have been recently developed and published.^{5,33,45,53,110-112,139,145}

The first quality assurance study on the rapid detection of LASV RNA included 24 participant laboratories from 17 countries; 10-fold dilutions of LASV-inactivated genetic material were detected with success varying from 21% to 85%, depending on the concentration in the sample.¹⁰⁸ Of interest is that specimens containing high concentration of viral RNA may lead to false-negative results by the inhibition of enzymatic reaction, suggesting that clinical specimens should be either spiked with internal control to monitor enzymatic reaction efficacy or tested after dilution.^{39,108} A second EQA for LASV detection was organized and showed that molecular diagnosis remains challenging, and that none of the participants used probe-based real-time RT-PCR assay because of the lack of a suitable protocol.¹⁰⁹

Indirect Diagnosis

Serologic diagnosis is made by demonstration of a fourfold rise in the titer of specific antibody. A high IgG antibody titer or the presence of specific IgM is indicative of a probable case. Nucleocapsid antigens are shared by most of these viruses, and quantitative relationships show the basic split between the viruses of Africa and the Western Hemisphere. Individual viruses immunologically are distinct by neutralization test, which depends on the specificity of epitopes contained in the envelope glycoproteins G1 and G2. Samples collected for serologic diagnosis can be kept at -20°C. Blood obtained in early convalescence may be infectious despite the presence of antibodies and should be handled accordingly. Antibodies often are detected by indirect immunofluorescence because it is an inexpensive, rapid, and sensitive test. An alternative is ELISA, the specificity of which is greater than and the sensitivity of which is on the level of the neutralization test. ELISA is therefore the test of choice for differentiation of viral strains of arenaviruses, for confirmation of unexpected results, and for detection of infection from the distant past. All these tests have been tested in the conditions of an outbreak and shown to be effective.

Antibodies specific to South American arenaviruses appear 12 to 30 days after onset, which often correlates with clinical improvement.¹¹⁷ Traditionally, Lassa fever has been diagnosed using antibody detection assays, including indirect immunofluorescence (IIF) and ELISA. IIF, however, has many false-positive results, especially for IgM antibodies, which in addition to being false positive, are known to persist for months to years in these settings and are therefore not of much value.⁷⁸

In the case of Lassa fever, antibodies detectable by immunofluorescence appear early and often are present during the acute illness with no apparent relation to viremia or clinical status; 50% of patients with Lassa fever develop IgM or IgG antibody during the first week, and more than 66% do so during the next week. Antigen-detection ELISA in conjunction with IgM-capture ELISA has shown promise for rapid and sensitive diagnosis of Lassa fever. Neutralizing antibodies usually develop only after 4 to 6 months of convalescence.

PROGNOSIS AND TREATMENT

Prognosis

The case-fatality ratio of AHF, which is greater than 15% without specific treatment, drops spectacularly to less than 1% when specific treatment is available.⁶⁶ Granulocyte colony-stimulating factor serum level seems to be a marker of severity of the illness.⁹³

For Lassa fever, no correlation exists between antibody levels and outcome. Viremia levels in Lassa fever are important in terms of prognostic value; the higher the viral concentration, the higher the mortality rate. The serum aspartate transaminase level also is an accurate prognostic marker; values above 150 U/mL are associated with a 55% mortality rate, whereas the overall mortality rate is approximately 15%.⁷⁴

Treatment

Arenaviral hemorrhagic fever should be managed by monitoring and correction of fluid, electrolyte, and osmotic imbalances and of metabolic acidosis. Hydration should be administered cautiously because of generalized capillary leak and the possibility of precipitating pulmonary edema. If possible, bleeding should be treated with clotting factor and platelet replacement as guided by laboratory test results.

For Junín virus infection, immune serum therapy is effective in reducing the incidence of mortality when it is given within the first 8 days of illness.^{42,43,91} Experimental evidence suggests that the plasma may work through attacking infected cells as well as viral neutralization. In approximately 10% of patients with AHF due to Junín virus who are treated with immune plasma develop an entity called "late neurologic syndrome," with symptoms that include fever, cerebellar signs, and cranial nerve palsies. These clinical signs are transient; they are thought to be related to immunopathologic mechanisms induced by the treatment with convalescent plasma. Surprisingly, this late neurologic syndrome has not been noted in patients with AHF who recover without administration of immune plasma therapy.⁷⁸

Despite the recognized efficacy of convalescent plasma for treatment of Machupo virus infection, the paucity of survivors and the lack of programs for collection and storage of BHF immune plasma anticipate the problem of shortage in case of a new outbreak. In recent cases, ribavirin was offered to two patients presenting with life-threatening infection; both recovered without sequelae. These promising results suggest the need for performing more extensive clinical studies to assess the usefulness of ribavirin for treatment of BHF.⁷⁹

Junín and Guanarito viruses showed very high in vitro sensitivity to ribavirin, which also showed antiviral effect in patients.^{43,44} One of the laboratory-acquired Sabiá virus infections was treated successfully with ribavirin; the treatment was started early after onset, and there was no production of neutralizing antibodies.

The late evolution and low titers of LASV neutralizing antibodies render immune serum-based therapy less efficient than in treatment of South American arenaviral fevers.⁷⁵ In contrast, clinical studies have shown ribavirin to be of benefit in severe cases and that it therefore should be used as early as possible in the course of the disease. Ribavirin, a guanosine analogue, has broad-spectrum antiviral activity and, if given within the first 6 days of onset of symptoms, has been shown to decrease the mortality of severe Lassa fever from 55% to 5%. Oral ribavirin has also been used but is less effective than the intravenous form because it can take 2 to 4 weeks of administration to achieve steady-state levels.⁶ The intravenous regimen that is recommended for treatment of LASV is as follows:

- A loading dose of 30 mg/kg, then
- 15 mg/kg every 6 hours for 4 days, then
- 7.5 mg/kg every 8 hours for 6 days.

A well-recognized side effect of ribavirin is hemolytic anemia, which is reversible when drug administration is interrupted. It is also important to note that the half-life of ribavirin is about 24 hours. The large volume of distribution indicates that the drug will still have an effect long after cessation. The mechanism of action of ribavirin consists of interference of RNA capping, RNA polymerase inhibition, and lethal mutagenesis.⁶

Postexposure prophylaxis (PEP) with oral ribavirin has also been discussed. Patients who had a definitive high-risk exposure—including (1) penetration of skin by a contaminated sharp instrument, (2) contamination of mucous membranes or broken skin with blood or bodily secretions, (3) participation in emergency procedures, or (4) prolonged and continuous contact in an enclosed space without appropriate use of personal protective equipment—may all be examples of when ribavirin PEP is indicated. The following oral regimen for adults has been proposed:

- Ribavirin 35 mg/kg loading dose (max: 2.5 g), followed by
- Ribavirin 15 mg/kg by mouth 3 times per day for 10 days.⁶

There are many other experimental antiviral drugs that have been tested in vitro or even in small animal models for activity against LASV, but none have progressed into clinical trials for Lassa fever. One particular drug is favipiravir (T-705), which is an RNA polymerase inhibitor that has also been studied for its effectiveness in the recent Ebola epidemic.⁷⁸

The Future of Antivirals in the Domain of Arenaviruses

In the past 5 years, basic research has used reverse genetics to develop replicons and infectious clones that are used to investigate virus replication mechanisms, to test antivirals in vitro, and to better understand arenavirus cycles. The development of reverse genetic systems allows detailed molecular characterization of the viral *cis*-acting signals and *trans*-acting factors that control each of the steps of the virus cycle, including RNA synthesis, packaging, and budding. Likewise, the ability to generate predetermined specific mutations in the genome and to analyze their phenotypic expression will contribute to elucidation of the arenavirus-host interactions as well as the mechanisms leading to severe hemorrhagic disease in humans. The development of a mini-replicon system for LASV will help the investigation of replication and transcription and may facilitate the testing of antivirals outside biosafety level 4 laboratories.⁶⁷

Infectious LCM virus has been recovered entirely from cDNA. Intracellular transcription from polymerase I-driven vectors and co-expression of the minimal viral *trans*-acting factors NP and L from polymerase II-driven plasmids resulted in the efficient formation of infectious virus with genetic tags in both genome segments; this cDNA-derived virus behaves identically to wild-type virus in both cell culture and infected mice.⁴⁹

High-throughput screening of molecules for their antiviral effects is being performed increasingly by both public laboratories and private companies. From 2003 to 2006, seven articles reporting testing of molecules with antiviral efficacy on arenaviruses were published.^{1,4,8,19,21,63,140} In recent years research activity in antivirals against these viruses has accelerated.^{20,26,81,99,100,107,122,130,141} Unique small molecules have been identified as inhibitors of arenavirus infection. They prevent arenavirus entry and protect against risk of lethal infection in animal models.⁷⁸

PREVENTION AND CONTROL

Prevention of arenavirus disease consists of preventing transmission from rodents to humans, from humans to humans, and from infected specimens to laboratory personnel. It seems that patients pose minimal risk of contagion in early stages of disease. However, as the process continues and viremia increases, the opportunities for spread rise as well. Strategies for avoiding contact between rodents and humans have been effective in BHF.⁸⁹ Simple trapping of *C. callosus* in towns was successful in reducing human contact and thus reducing the disease to essentially zero. This is more difficult in AHF because conditions under which human exposure occurs are different from those in BHF. *C. musculinus* (reservoir of Junín virus and AHF) distribution is much wider than that of *C. callosus* (reservoir of Machupo virus and BHF), and Argentine agricultural practices continue to place workers at risk for exposure to reservoir hosts.

A collaborative effort conducted by the United States and Argentine governments led to the production of a live attenuated Junín virus vaccine named Candid #1, which has passed safety and immunogenicity tests in U.S. volunteers. Its efficacy was established in a double-blind trial in 15,000 agricultural workers at risk for natural infection in Argentina. Subsequently, more than 100,000 persons were immunized with Junín virus vaccine in Argentina. Currently the vaccine is approved in Argentina for adults older than 15 years of age.⁷⁸ Animal protection studies suggest that the Junín vaccine could be protective against Machupo virus infections as well. A prospective study conducted during two epidemic seasons among 6500 male agricultural workers in Argentina showed that Candid #1 vaccine efficacy was 84% or higher and that no serious adverse effects could be expected.⁹²

Neutralizing antibody titers to Candid #1 vaccine against AHF were studied for 2 years after vaccination in 330 volunteers. Of a total of 160 volunteers who received Candid #1, 54 had no detectable reinfection with arenaviruses, 55 had preexisting antibodies to Junín virus, and 51 had preexisting antibodies to LCM virus; the remaining 170 individuals received placebo. Levels of anti-Junín virus antibodies displayed a trend in which titers increased with the virulence of the infecting strain, from Candid #1 through subclinical Junín virus infection, vaccination after subclinical infection, and Junín virus symptomatic infection. The study also demonstrated that the mean titer of neutralizing antibodies to Candid #1 did not vary significantly during the 2 years, was significantly lower than that elicited by wild strains of Junín virus, significantly increased the titers of preexisting anti-Junín antibodies, and was not modified by preexisting anti-LCM virus antibodies.³

Comparative sequence analysis of the L RNA segment of Candid 1 strain and the more virulent ancestors (XJ 44 and XJ 13) revealed 12 point mutations in the L polypeptide that are unique to the vaccine strain.⁶⁰ Whether these changes are associated with the attenuated phenotype remains to be investigated by the use of reverse genetic systems.

For VHF, no preventive measures have been developed. Attenuated Junín virus strains do not protect experimental animals against challenge with Guanarito virus. In VHF, the evidence suggests that transmission occurs around houses and in fields as in BHF, so measures to avoid contact between rodents and humans should be effective, as shown for BHF.

For Lassa fever, reducing the contact with *Mastomys natalensis* is a formidable task in West Africa, and this option does not seem to have a promising future. Because person-to-person transmission has been reported in Lassa fever, precautions should be taken to place patients in single rooms. The health care team should be small and adequately trained; they should wear appropriate personal protective equipment including gloves, gowns, and filter masks.^{22,24,25} All secretions should be decontaminated.⁸⁴ Laboratory procedures should be performed with care by use of inactivating methods of heat, chemicals, or irradiation.

In rhesus monkeys (*Cercopithecus aethiops*), the humoral antibody response measured after they were challenged with purified inactivated LASV, although as high as in humans who recovered from Lassa fever, was insufficient to protect the animals from a fatal outcome.⁹⁶ A naturally attenuated strain (Mopeia virus, from Mozambique) protects rhesus monkeys against challenge with LASV, but field studies are required to establish the extent and nature of natural human infection with this virus before it can be considered seriously as a candidate for human vaccine development. Alternative approaches, including the use of vaccinia virus vectors bearing the LASV GPC or N gene, are being investigated actively and show promising preliminary results.^{46,47} Two peptides encoded by the glycoprotein precursor were shown to display high-affinity binding to human leukocyte antigen (HLA)-A*0201 transgenic mice; mice immunized with these peptides were protected against challenge with a recombinant vaccinia virus that expressed LASV glycoproteins. These two epitopes represent candidates for inclusion in epitope-based vaccine constructs.⁹

The Future of Vaccine Research

Although there is currently no licensed vaccine against LASV, in recent years tremendous advances have been made toward vaccine development.^{10,34,41,59,62,80} Many different approaches were used. Reverse genetic

exchange of the viral glycoprotein for foreign glycoproteins created attenuated vaccine strains that remained viable although unable to cause disease in infected mice; this phenotype remained stable even after extensive propagation in immunodeficient hosts. The engineered viruses induced T-cell-mediated immunity, protecting against systemic infection and severe liver disease on wild-type virus challenge.⁷ The yellow fever vaccine 17D has been used as a vector for the LASV glycoprotein precursor, resulting in construction of recombinant virus, which was replication competent and processed LASV glycoprotein in cell culture. The recombinant virus replicated poorly in guinea pigs but still elicited specific antibodies against Lassa and yellow fever antigens, and single subcutaneous injection protected guinea pigs against fatal Lassa fever.¹³ Clone ML29 is a reassortant virus that encodes the nucleocapsid protein and glycoproteins from LASV and the RNA polymerase and matrix protein of Mopeia virus; replication of ML29 was attenuated in guinea pigs and nonhuman primates. Guinea pigs vaccinated with ML29 survived after challenge with LASV without developing either signs of disease or histologic lesions. Rhesus macaques inoculated with clone ML29 developed primary virus-specific T cells capable of secreting interferon in response to homologous and heterologous challenge (the latter with Mopeia virus and LCM virus). Vaccinated monkeys did not present any histologic lesions or signs of disease.⁸⁶ Future strategies should focus on continuing the development of human monoclonal antibodies for passive immune therapy for the South American hemorrhagic fevers and to develop antivirals for Lassa fever and Argentine hemorrhagic fever as well. There should also be follow-through with several advanced Lassa fever vaccine candidates.

Filoviral Hemorrhagic Fever: Marburg and Ebola Virus Fevers

Amy S. Arrington • David Hilmers • Judith R. Campbell • Gail J. Harrison

I came to understand firsthand what my own patients had suffered.... I was isolated from my family and I was unsure if I would ever see them again. Even though I knew most of my caretakers, I could see nothing but their eyes through their protective goggles.

**Dr. Kent Brantly, medical missionary,
Ebola survivor, Senate Hearing on
Ebola Outbreak, September 16, 2014**

Hemorrhagic fevers due to Marburg and Ebola viruses, are among the most virulent infections known to mankind.⁴⁷ Ebola virus disease (EVD) and outbreaks are associated with high attack rates and substantial mortality and until recently were only encountered by those in remote, rural areas of sub-Saharan Africa or maximum security infectious disease laboratories such as the US Army Medical Research Institute of Infectious Diseases (USAMRIID). For decades these pathogens were studied at institutions such as USAMRIID because of the biohazard of Marburg and Ebola viruses and their potential use as biologic weapons.^{21,135} On the other extreme, the public, mostly unaware of this exotic disease, became familiar with this rare infection through novels such as Richard

Preston's *The Hot Zone*, which vividly described the devastating effects of this disease.¹⁴⁰ In 2014, this drastically changed. The impact of viral hemorrhagic fever, specifically due to Ebola virus, became known to people worldwide. Scientists, health care workers, public health officials, politicians, and the general public became familiar with this rare but devastating infection. Viral hemorrhagic fever is actually caused by viruses from four diverse viral families: Arenaviridae, Bunyaviridae, Flaviviridae, and Filoviridae. *Ebolavirus* and *Marburgvirus* are the only genera of the family Filoviridae, which belongs to the order Mononegavirales.⁴⁴ Human outbreaks of acute hemorrhagic fever caused by these viruses are associated with case fatality rates of up to 88%. The outbreak of 2014 demonstrated the high potential for large-scale dissemination, high rates of mortality, potential for major public health effects, public panic, social disruption, and necessity for special preparedness globally. Furthermore, this most recent Ebola outbreak exposed gaps in infrastructure and processes for global public health emergencies.⁵⁵ *Ebolavirus* and *Marburgvirus* are classified as Biohazard Level 4 and Biothreat Category A agents; thus, they should be manipulated only in maximum-security facilities. Research performed decades earlier at such

facilities provided the scientific foundation for diagnostic assays, therapeutic options, and candidate vaccines employed during the 2014 outbreak.^{107,60} This established scientific evidence then contributed to an unprecedented rapid review and FDA approval of candidate vaccines and therapeutic agents.²⁰²

ETIOLOGIC AGENTS

The *filovirus* family consists of three different genera, *Ebolavirus*, *Marburgvirus*, and *Cuevavirus*. Although all members of this family cause highly lethal viral hemorrhagic fevers, Ebola virus has proven to be a pathogen capable of large-scale human morbidity and mortality, with mortality rates ranging from 30% to 90%. The most recent Ebola virus epidemic in 2014–15 affecting West Africa and beyond has reminded us of the virulence of these agents, as well as provided new knowledge regarding the pathogenesis and potential treatments for this biologic threat.

Members of the Filoviridae all have similar morphologic features. The viral particles are filamentary and often form bizarre configurations, such as “6”-shaped forms and hairpins (Fig. 187.1), and may be up to 14,000 nm in length.^{44,148} In contrast, the filaments are always 80 nm wide. The capsid contains a single negative-stranded RNA genome that encodes seven structural proteins and one nonstructural protein, the soluble glycoprotein.^{149,184,183} Members of the Filoviridae family are enveloped, nonsegmented, single-stranded negative-sense long (~19 kb) RNA genomes with a uniform 80-nm diameter. They contain seven sequentially arranged genes and are distinguished by virions that are a characteristically filamentous shape (see Fig. 187.1). Filoviruses replicate readily in Vero, MA-104, or SW-13 cell cultures, all of which are derived from primates. These viruses are highly pathogenic for macaques. To date, there are seven designated species within the three genera in the Filoviridae family, with eight identified viruses (Table 187.1). Of these eight viruses, six are known to cause disease in humans, with Zaire Ebola virus being the virus responsible for the largest outbreak yet in the world, with more than 28,000 cases and more than 11,000 deaths to date (Centers for Disease Control and Prevention [CDC] case count, 2016). The evolutionary profile of Filoviridae suggests that Marburg virus and Ebola virus represent distinct filovirus lineages. Within the species of Ebola virus, there is a high degree of genetic stability, indicating a high level of fitness adapted to their respective niches.

Lloviu virus, obtained from bats in Spain (2002), is the only known virus in the Cuevavirus family, and its potential to cause human infections remains undetermined as no virus has yet been isolated.¹²⁸ This review is therefore limited to Ebola virus and Marburg virus.

Virtually no antigenic relationship exists between Marburg virus and any of the Ebola virus species. Virus neutralization has been virtually impossible to measure for any of the filoviruses, which has hindered epidemiologic and ecologic studies of these agents. Only the three African Ebola virus species appear to be pathogenic for humans. Interestingly, these strains are also the only Ebola species originating and circulating in Africa. Unlike these three Ebola species, *Reston Ebola*

virus is found only in the Philippines among nonhuman primates, and although antibodies to Reston Ebola virus has been detected in those exposed, it has not been found to cause disease in humans.⁷² These four Ebola virus species exhibit extensive cross reactivity in immunofluorescence methods and enzyme-linked immunosorbent assays (ELISAs). Filoviruses are classified as biosafety level 4 agents (BSL-4), based on their easy person-to-person transmission, high mortality rate, and lack of approved vaccine or drug therapies (www.cdc.gov/nceid/dhcpp/vspb/).^{80,208}

HISTORY AND EPIDEMIOLOGY

Marburg Virus

Marburg hemorrhagic fever was first described after concurrent outbreaks of this unusual, severe infection among laboratory workers in Marburg and Frankfurt, Germany, and Belgrade, Yugoslavia, in 1967 (see Table 187.1).^{117,115,160,199} Seven of 31 patients died, and the source was determined to be African green monkeys (*Cercopithecus aethiops*) that had been exported from Uganda and shipped to laboratories in all three locations. The etiologic agent was isolated, characterized, and identified by scientists in Marburg and Hamburg and later named *Marburg virus* after the city with the most cases.^{1,2} For decades sporadic outbreaks of Marburg occurred in rural villages in several African countries including Kenya, Democratic Republic of the Congo (formerly known as Zaire), and Angola. Civil war and political unrest hindered detailed characterization of these outbreaks other than the notably high case fatality rates.^{57,156}

A lengthy outbreak occurred between 1998 and 2000 in Durba (eastern Democratic Republic of the Congo), affecting 154 people and killing 83% of victims (Fig. 187.2).¹³ Most patients (94%) worked in underground gold mines. Because of the civil war raging in 1997, the cause of the outbreak was not identified until 1999, a year after the first cases occurred. The Durba outbreak was characterized by the circulation of multiple viral strains, pointing to several independent introductions from the unknown natural reservoir.^{12,13} The largest recorded Marburg outbreak occurred in Uige Province of northern Angola. It was the first recorded outbreak in the west side of Africa and lasted from October 2004 to July 2005, causing 252 cases and 227 deaths (fatality rate, 90%).^{26,199} Complete genomic characterization showed that the culprit strain, named *Angola marburgvirus*, was closely related to previous East African isolates.^{171,172,176,183-186,196-198} In 2007, a small outbreak of Marburg hemorrhagic fever among mine workers in Kamwenge District of Uganda was reported. In 2008, two cases of Marburg hemorrhagic fever occurred in tourists who visited the Python Cave, a bat cave in Queen Elizabeth National Park in western Uganda.¹⁹⁹ One of these had a rapidly fatal disease. The last reported outbreak of Marburg occurred in Uganda in 2012 during which there were 26 confirmed or probable cases and 15 (58%) fatalities. In November 2014 there was a single confirmed, fatal case of Marburg hemorrhagic fever in Kampala, Uganda. Investigation of 197 contacts and testing of 8 suspect cases were all negative.¹⁹⁰ The Viral Special Pathogens Branch of the CDC hosts a web page with archived and current outbreak postings, case counts, and location lists of viral hemorrhagic fevers (www.cdc.gov/vhf/marburg/outbreaks/index.html) reported from around the world.

Confirmed cases of Marburg hemorrhagic fever have been sporadically reported in Uganda, Zimbabwe, the Democratic Republic of the Congo, Kenya, and Angola. It characteristically occurs in outbreaks. However, cases of Marburg hemorrhagic fever outside of Africa have been reported infrequently, in laboratory workers and travelers. The emergence of the other filoviral cause of hemorrhagic fever, *Ebola virus*, has surpassed Marburg in the regional and global impact.

Ebola Virus

1976 to 1979: First Recorded Ebola Outbreaks

Ebola first emerged in the form of two nearly simultaneous outbreaks in 1976, one caused by *Sudan ebolavirus* and the other by *Zaire ebolavirus*. The first outbreak was due to *Sudan ebolavirus* and occurred in Sudan, near the border with the Democratic Republic of the Congo, mainly affecting the towns of Nzara and Maridi.^{126,157} The first cases were reported among cotton factory workers, but spread to household contacts and

^cAs of May 2017.

health workers who cared for them during their illness. The outbreak spread from Nzara to Maridi through exposed persons who were incubating this infection and were later hospitalized in Maridi. Hospitalization of these cases resulted in transmission within the hospital in Maridi and then throughout the township among close contacts of those sick and dying of Ebola. The disease in Maridi was particularly amplified because of transmission in the very large and busy hospital due to use of nonsterile needles and syringes.⁹⁰ The outbreak had 284 cases, and the mortality rate was 53%, a proportion characteristic of *Sudan ebolavirus* infection. The outbreak due to *Zaire ebolavirus* occurred in the Democratic Republic of the Congo, near the border with Sudan, 2 months later.⁹⁰ The epicenter was Yambuku, about 800 km from Nzara. This previously unknown disease was named for the river Ebola, which flows past Yambuku. The initial cases were people who had received recent injections at an outpatient clinic; many were women attending prenatal and outpatient clinics. In this outbreak the majority of cases were thought to be due to reuse of nonsterile needles and syringes, although close contact with those dying of Ebola was also associated with secondary cases. There were 318 cases, and the mortality rate was 89%, characteristic of *Zaire ebolavirus* infection. Later, an unconfirmed lethal case was reported involving a 9-year-old girl living in Tandala, Democratic Republic of Congo,^{61,76} followed by another *Sudan ebolavirus* outbreak in 1979, again in Nzara, with 34 cases and 22 deaths.⁹

Reston Ebolavirus

In 1989, it became apparent that Ebola virus is not restricted to Africa. A group of cynomolgus monkeys (*Macaca fascicularis*) from the Philippines, quarantined in a laboratory in Reston, Virginia, developed a lethal hemorrhagic disease.⁸⁷ Virions antigenically similar to Ebola virions were detected in tissues, and Ebola virus infection was confirmed by culture in Vero cells. In the following weeks, the introduction of new monkeys and the spread of the infection to several animal rooms meant that the entire cohort of more than 400 animals had to be destroyed. The building was fumigated and abandoned. The virus was recovered from another macaque in Philadelphia and later in a laboratory in Italy.¹³⁴ Although no humans fell ill during these episodes, several monkey handlers in the United States were shown to have seroconverted. In 1996, a cynomolgus monkey imported from the Philippines died in an animal facility in Texas, where two additional cases subsequently occurred, all caused by *Reston ebolavirus*.¹⁴⁵

1994 to 1997: Ebola Resurgence

After a 15-year period in which no human cases were recorded, Ebola reemerged in 1994 for a 3-year period. These outbreaks occurred in more populated areas of Gabon and Zaire and for the first time in West Africa. This new phase was marked by the identification of a new species, *Ivory Coast*, and by four *Zaire ebolavirus* outbreaks. The only case caused

FIG. 187.2 Geographic distribution of human outbreaks of Marburg virus fever in Africa.

by *Ivory Coast ebolavirus* occurred in 1994, when an ethnologist was sickened a few days after performing an autopsy on a chimpanzee found dead in Tai National Park in Ivory Coast.^{51,105,106} A large outbreak then occurred in 1995, in and around the town of Kikwit in the southern Democratic Republic of Congo,¹³³ with 315 cases and a mortality rate of 81%. Despite the deployment of more sophisticated scientific and medical resources than were available in 1976, this outbreak was as large as the 1976 one, probably because it affected a town of several hundred thousand inhabitants and person-to-person transmission occurred mainly in two hospitals. Three other outbreaks, all from *Zaire ebolavirus*, struck northeast Gabon between 1996 and 1997.⁶⁸ The first occurred in northeastern Gabon, close to the border with Cameroon,³ in three gold-digger camps located in the heart of the forest. Some of the victims left the camps for the nearest hospital, located in Makokou, where they infected other patients and caused a second wave of virus dissemination. In total, 49 clinical cases and 29 deaths were recorded. The second outbreak hit the village of Mayibout, located south of Mekouka.⁶⁸ The first victims were 18 children who had helped carry and butcher a chimpanzee carcass found in the forest. These 18 children infected their families and friends, who in turn transmitted the disease to neighboring villages. In total, this outbreak involved 31 people and caused 21 deaths. The third outbreak in this region occurred between October 1996 and March 1997.⁶⁸ It started among hunters, who infected a traditional healer, his assistant, and some of his patients, who in turn transmitted the disease to several towns and villages in Gabon. Fifteen cases and 11 deaths were recorded in Libreville, and a South African nurse was infected by a Gabonese physician who had traveled to Johannesburg. This outbreak, with 60 cases and 45 deaths occurring in a 6-month period, was noteworthy for its wide geographic range. Although sporadic, these outbreaks in the 20th century provided a basic understanding about the epidemiology, pathogenesis, treatment, and complications of this rare and deadly infection.¹⁵¹

2000 to 2004: Geographic Pattern of *Zaire Ebolavirus* and *Sudan Ebolavirus* Resurgence

***Zaire ebolavirus* outbreaks.** The first outbreak during this period occurred in northeast Gabon and northwest Democratic Republic of Congo between October 2001 and May 2002.¹¹¹ It spread along the main road between Mekambo (Gabon) and Mbomo (Democratic Republic of Congo) and, in fact, involved several independent epidemic chains of human-human transmission with different source animals.¹¹⁰

These epidemic chains started when local hunters found and manipulated the carcasses of an antelope, chimpanzees, and gorillas. Simultaneously, a second outbreak occurred in the Democratic Republic of Congo, in villages close to the Gabonese border, 200 km south of Mbomo. It then spread to the town of Kelle, about 65 km away. The origin of this outbreak is unknown. The third outbreak also affected the region of Mbomo, between 2002 and 2003.⁵⁴ It had two independent sources resulting in two separate chains, one in Mbomo and the other in Kelle. This outbreak involved 143 cases and caused 128 deaths. The fourth outbreak again affected the region of Mbomo, in late 2003; the first cases occurred in Mbanza, a village located about 30 km north of Mbomo. In this outbreak, 35 cases and 29 deaths were recorded.¹⁹⁶ Two years later, in 2005, an outbreak occurred in Etoumbi, 60 km south of Mbomo, where 12 cases and 9 deaths were reported. Simultaneously with the human outbreaks, *Zaire ebolavirus* also infected animals belonging to several species, including gorillas, chimpanzees, and duiker antelopes, probably accounting for the sharp declines in animal populations observed in these regions between 2001 and 2005.^{81,110,186}

***Sudan ebolavirus* outbreaks.** Two outbreaks of *Sudan ebolavirus* also occurred during this period (Fig. 187.3). One occurred in Uganda in 2000, causing 173 deaths among its 425 victims (mortality rate, 41%).¹⁹⁶ It was the largest of all recorded *Sudan ebolavirus* outbreaks and comprised three foci, one in the immediate area of Gulu, one in the town of Masindi, and one in Mbarara; of note, the index patient in the Mbarara focus was a soldier. A second *Sudan ebolavirus* outbreak occurred in Sudan in 2004 in the town of Yambio, located only a few dozen kilometers from Nzara and Maridi, which had been sites of Ebola virus outbreaks in 1976 and 1979. In this outbreak, 17 cases and seven deaths occurred.¹⁹⁷

2007 to 2012: *Ebola* Outbreaks

In 2007, an outbreak of 264 cases of Ebola hemorrhagic fever caused by *Zaire ebolavirus* species was reported in the Democratic Republic of Congo. In this outbreak, 187 deaths occurred and the mortality rate was 71%. In Uganda in late 2007 and early 2008, 149 cases of Ebola hemorrhagic fever, caused by a new strain, *Ebola Bundibugyo*, was reported from the Bundibugyo District. In this outbreak, 37 deaths occurred, with a mortality rate of 25%. In November 2008, the first known occurrence of *Reston ebolavirus* strain in pigs was reported from the Philippines, with asymptomatic transmission to six human workers (no fatalities) in contact with the pigs.^{94,114} In December 2008 through

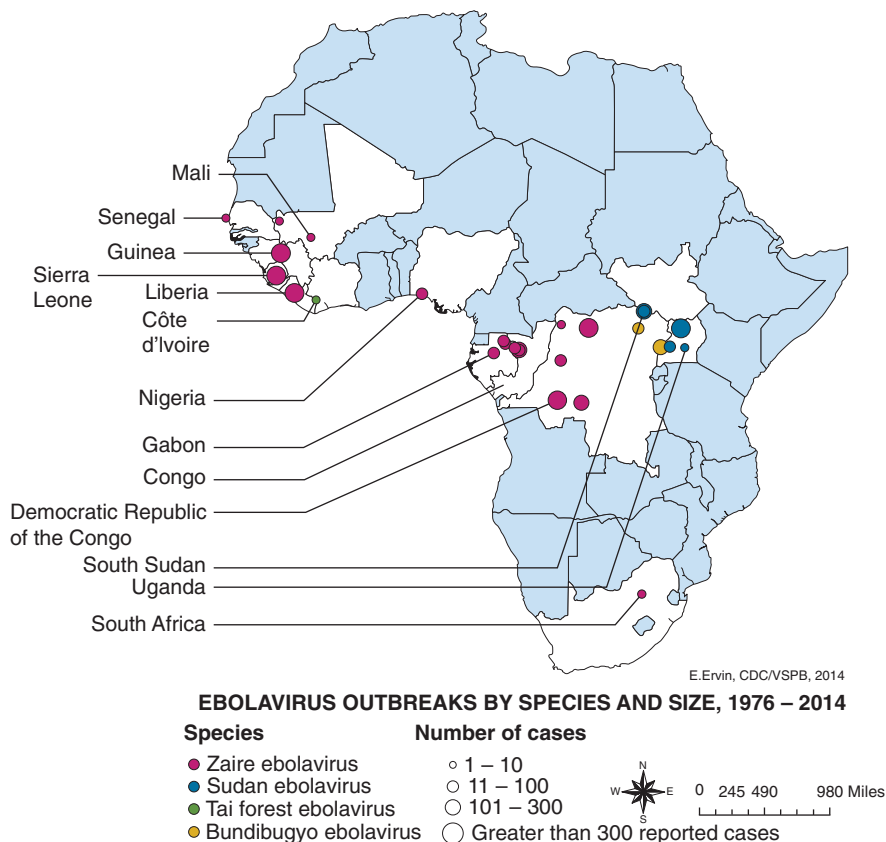

FIG. 187.3 Cases of Ebola Virus Disease in Africa, 1976–2016. (Courtesy Elizabeth Ervin, Centers for Disease Control and Prevention, Viral Special Pathogens Branch, 2014.)

February 2009, 32 human cases of Ebola hemorrhagic fever caused by the *Zaire ebolavirus* strain, resulting in 15 deaths (47% mortality rate), were reported from the Democratic Republic of Congo. In 2011, one case of Ebola hemorrhagic fever was reported from Uganda and quickly contained, with no other known cases from that incident reported. In 2012, Uganda reported an outbreak of Ebola hemorrhagic fever in the Kibaale District with 24 human cases and 17 fatalities, and Democratic Republic of Congo reported 35 confirmed cases of Ebola hemorrhagic fever, 12 of them fatal. The Viral Special Pathogens Branch of the CDC hosts a webpage with archived and current outbreak postings, case counts, and location lists of viral hemorrhagic fevers (www.cdc.gov/vhf/Ebola/outbreaks/2014-west-africa/index.html) reported from around the world.

Largest Ebola Outbreak in History (2014–15)

Previously recorded Ebola outbreaks consisted of seven to 425 cases each and were limited to one or two countries. Even in these resource limited settings transmission was contained. The Ebola epidemic of 2014–15 was unprecedented in several ways. The number of cases in this single epidemic surpassed the total of all previous Ebola epidemics combined (see Table 187.1). Within 6 months of the index case, there were more cases of Ebola than all previous Ebola outbreaks combined, and for the first time in history, the Ebola outbreak was in a capital city.⁸⁹ The rapidity with which infection spread through villages, communities, and even to other countries was unprecedented and exposed deficiencies in national health care infrastructures and organizations globally. Although the majority of cases occurred in West Africa, this epidemic had global impact and implications, as cases were diagnosed or treated in seven countries outside of West Africa. Detailed interviews and investigation of events conducted by the World Health Organization (WHO) and other international agencies and institutions significantly expanded our understanding of the epidemiology and pathophysiology of what was previously considered a rare and obscure infection. The rapid spread from Guinea to two other West African countries, Liberia and Sierra Leone, and infections in travelers presented unique challenges yet served as an opportunity to prospectively study this disease. Furthermore, this unprecedented outbreak served as an impetus for global preparedness

for responding to highly virulent pathogens. Despite heightened awareness and scientific advances as a result of this epidemic, other aspects of Ebola virus, such as the natural reservoir, best therapeutic interventions, and optimal postexposure prophylaxis, remain uncertain.

Guinea. The index case was a 2-year-old child in the remote Guinean village of Meliandou, Guéckédou. In December 2013, the child had fever, black stools, and vomiting and died 4 days later.^{34,167} Several family members, health workers, and those who attended his funeral developed similar symptoms and a rapidly fatal illness. Detailed case tracing in Guinea revealed that family and village caregivers, as well as health care workers in hospitals in Guéckédou and Macenta, were sources for additional cases before the outbreak was recognized. Complete genome sequences from three of these patients early in the epidemic had a high degree of similarity, suggesting a single introduction of the virus into this population.¹⁶⁷ When these sequences were compared to 48 sequences of filoviruses available from GenBank, the Guinean *Zaire ebolavirus* strain was closely related, yet a distinct clade, to strains from DRC and Gabon, and that evolution of the Guinean strain of Ebola virus emerged in parallel with strains from the DRC.^{167,70} Potential sources of Ebola virus in the epicenter of the 2014–15 epidemic include fruit bats (*Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*) which are prevalent in this part of West Africa. Studies conducted by Leroy et al sought to identify the source or reservoir of Ebola through trapping primates, bats, birds and small terrestrial vertebrates that were tested for evidence of infection by Ebola virus. Three different bat species had evidence of immunoglobulin G (IgG) specific for Ebola virus detected in serum. Furthermore, viral nucleotide sequences were detected in the liver and spleens of bats and clustered phylogenetically with the Zaire clade.¹⁰⁹ The child thought to be the index case lived near a hollowed-out tree which was a roosting place for fruit bats. Unfortunately, when the epidemiologist investigated this village, the tree had been burned down.¹⁴⁶ Factors that contributed to the unusual rapidity of the spread of this Ebola epidemic included: delay in early recognition and reporting of the outbreak, the crowded, urban setting at the epicenter, villages and cities connected by roads and limited public health resources and facilities in this poverty stricken area of West Africa. By March 2014 Ebola virus was reported for the first time in a West African capital city,

Conakry. From there a large number of transmission of cases occurred in Guinea and throughout the southeastern part of the country. From December, 2013 to December, 2015 there were 3814 suspected, probable or confirmed cases of EVD and 2544 deaths in Guinea. Once Ebola reached Conakry there was a large nosocomial outbreak affecting health care workers at the Hôpital de l'Amitié Sino-Guinéenne. One third of the initial cases at that Ebola treatment unit were health care workers. The other groups most often infected were household members of confirmed cases and burial workers. The observed mortality in Conakry was reported to be 43%.⁵ On December 29, 2015, WHO declared Guinea free of Ebola virus transmission after 42 days (two incubation periods) had passed since the last Ebola patient tested negative.^{27,200} Unfortunately, recent cases have been reported in Guinea. In this report sexual exposure to an EVD survivor was the only epidemiologic link to the new case. At the time, there were no other EVD cases in Guinea. Ebola virus RNA was detected in seminal fluid of the survivor 531 days after onset of disease and was genetically identical to that of the new case, his sexual partner. This report highlights the fact that Ebola virus remains viable and infectious during the long-term persistence.¹⁷

Ebola spread rapidly to other countries within 3 months of the index case. Transmission to neighboring countries was fueled in part by interconnection of these communities and villages with access across open borders via roads and pathways in even the most rural areas. In addition, within these communities some who had been exposed to Ebola in Guinea sought medical care in Liberia and Sierra Leone. People in these three countries often travel across the borders to visit family or seek care from traditional healers. Some had attended funerals in Guinea and then returned to Liberia and Sierra Leone incubating Ebola. It was not until March 2014 that the Ministry of Health of Guinea notified WHO of a rapidly evolving outbreak of Ebola virus disease in Guekedou, Macenta, Nzerekore, and Kissidougou districts, forested areas south of eastern Guinea and the capital Conakry. After this notification, neighboring countries were alerted, but the virus had already been introduced into the populations of Liberia and Sierra Leone.^{34,192}

Liberia. In March 2014, Liberia was alerted of the EVD outbreak in neighboring country of Guinea. The first cases of EVD in Liberia occurred 1 week after reports of EVD in Guinea.¹⁷⁰ There were 20 suspected cases reported and thought to be contained in Lofa and Margivi counties. Months later in May 2014, cases reemerged and rapidly spread to the capital city, Monrovia, by June 2014 and throughout the country by September 2014. Between March 2014 and January 2016, when Liberia was declared Ebola free, there were 10,678 suspected, probable, or confirmed cases of EVD and 4810 deaths. Core interventions from local government and international entities included the building of treatment centers, implementation of local communication and social mobilization, case management and surveillance, and hygienic measures. The decline in the number of cases coincided with community leadership in control efforts and changing of beliefs and burial practices in the population.³³

Sierra Leone. The coastal country of Sierra Leone shares national borders with Guinea to the north and east and Liberia to the south and is connected to Monrovia by roads and rivers. The first case of EVD in Sierra Leone was on May 25, 2014.^{34,200} These initial cases were detected soon after introduction into the country because of a clinical research program on Lassa hemorrhagic fever at the Kenema Government Hospital. This hospital, being in close proximity to the epicenter of the Ebola outbreak in Guinea, had mobilized and established surveillance and diagnostic capabilities given the existing hemorrhagic fever program. Investigation of the first case in Sierra Leone revealed an epidemiologic link between this case and the burial of a traditional healer who had treated several EVD patients from Guinea. Genomic sequencing of 78 cases in Sierra Leone was compared with that of three Guinean samples and suggested that two genetically distinct viruses from Guinea had been introduced into Sierra Leone.⁷⁰ The Lassa fever research program at Kenema Government Hospital provided infrastructure for clinical and laboratory evaluation for EVD for cases early in the epidemic in Sierra Leone.¹⁵¹ Observations from this site described clinical features and complications associated with the 2014 outbreak. Sierra Leone was initially declared free of Ebola in November 2015. However, two new confirmed cases were reported in January 2016.

Ebola outside West Africa. Another unprecedented feature of the Ebola epidemic of 2014 was the introduction of Ebola into seven countries

outside of West Africa from travelers or expatriate health care workers who had exposure to EVD while working in Ebola treatment units. Although most cases of EVD occurred within three countries in West Africa (Guinea, Liberia, and Sierra Leone), 36 cases and 15 deaths occurred in other African countries (Nigeria, Senegal, and Mali), Europe (Italy, Spain, and the United Kingdom) and the United States.²⁰⁰

The Nigeria EVD outbreak began on July 20, 2014, when a traveler from Liberia arrived in Lagos, Nigeria, and sought care for fever and body weakness. Although he denied exposure to a known EVD case or funeral attendance, his condition worsened, and on the third hospital day EVD was suspected and confirmed by PCR testing 2 days later. This index case transmitted Ebola to 13 first-generation contacts. Disease was spread to another large city, Port Harcourt, by one of these contacts, who traveled against medical advice and subsequently exposed three other individuals.^{49,129} From July to September 2014, there were 20 cases (eight fatal) in Nigeria. Although Lagos is the most populous city in Africa, the rapid deployment of epidemiologists, existing laboratory capacity, an established health care system led to an effective containment. Through aggressive tracing of first, second and third generation contacts of their index case, health officials in Nigeria were able to avoid widespread disease in this populous country.^{49,129}

The first laboratory-confirmed case of Ebola in the United States was diagnosed on September 30, 2014, in a Liberian traveler who was incubating the disease when he departed Liberia. He developed symptoms 5 days after arrival in the United States and sought care at a hospital in Dallas, Texas. Investigation by the CDC and local health authorities identified 48 contacts. Of these, 17 were persons with exposure to the patient in the community, 10 were persons who had been transported in the same ambulance that had transported the patient before it was completely cleaned and disinfected, and 21 were health care workers. All underwent direct active monitoring for 21 days. Although none of the community contacts developed disease, two nurses who provided direct patient care to the index case each developed fever and symptoms during this observation period. No secondary cases occurred in the contacts of these two health care workers.²⁸ These cases prompted detailed review of Ebola preparedness throughout the nation and multifaceted efforts on the local, state, federal, and global level.^{56,75} The fourth case of EVD diagnosed in the United States was in late October 2014, when a physician who had worked in an Ebola center in Guinea, returned to New York City. This case required monitoring of three close contacts and 114 health care personnel, none of whom developed disease.²⁰⁴

Additional cases of EVD outside of Africa occurred in Europe. Single cases occurred in Spain, Italy, and the United Kingdom in humanitarian health care workers who had worked in Ebola treatment centers in West Africa and returned to their home country. Given active monitoring for fever and symptoms, all were diagnosed early and isolated. There were no secondary cases reported in Europe.²⁰⁰

Latest Outbreak, 2017: Democratic Republic of the Congo

The most recent outbreak of EVD is in the Democratic Republic of the Congo (DRC). Initially, a small cluster of cases was first recognized on April 22, 2017, in the province of Bas Uélé, a remote forested area of the DRC, close to the border with the Central African Republic and some 1400 km northeast of the capital, Kinshasa. On May 9, WHO was first alerted of potential new EVD cases in this region, consisting of patients experiencing symptoms including hematuria, epistaxis, bloody diarrhea, and hematemesis. Rapid reverse-transcription polymerase chain reaction (RT-PCR) testing of samples conducted by the Institut National de Recherche Biomédicale (INRB) in Kinshasa confirmed Ebola Zaire virus. As of May 22, 2017, 29 cases had been confirmed, with three deaths, and more than 400 contacts were being actively monitored. To date, the outbreak is limited to a remote, geographically limited area of the DRC. This is the eighth Ebola outbreak in the DRC since 1976, where the virus was first isolated. The last outbreak of Ebola in the DRC's Boende region was in 2014, resulting in 49 fatalities.^{25,195}

Ebola and Marburg Virus Transmission

Animal to Human

The sources of most human outbreaks of viral hemorrhagic fever, including most Marburg outbreaks, the *Zaire ebolavirus* outbreaks that

occurred between 1976 and 1997, and all outbreaks of *Sudan ebolavirus*, have not been identified. Prior to 2014, there were 13 recorded outbreaks and two isolated cases of Ebola, totaling about 1850 human cases, and 1300 deaths had struck countries spanning the equatorial forest regions of Africa.¹⁹⁸ In the 2014–15 Ebola epidemic, there were 28,616 human cases and 11,232 deaths that occurred primarily in West Africa. A review of the epidemiologic surveillance during Ebola and Marburg hemorrhagic fever epidemics in Africa over a 15-year period delineated several factors that affected transmission.¹ During rural epidemics, multiple introductions of the virus into the human population through wildlife were observed. In contrast, during epidemics in more urban settings, the introduction of a single case in the community was responsible for epidemics.

Several outbreaks have been firmly linked to infected animal carcasses. The 1967 outbreak of Marburg virus infection in Marburg and Belgrade was linked to the handling of organs and tissues from vervet monkeys imported from Uganda.^{115,160} As mentioned before, an ethnologist became infected by *Ivory Coast ebolavirus* in 1994 while performing an autopsy on a chimpanzee.¹⁰⁶ Similarly, the 1996 Mayibout outbreak in Gabon started among children who found and butchered a chimpanzee carcass in the forest.⁶⁸ Likewise, the sources of the *Zaire ebolavirus* outbreaks that occurred in the border region of Gabon and Democratic Republic of Congo between 2001 and 2003 are well documented; they all occurred after people handled animal carcasses they had found in the forest (mainly gorillas, chimpanzees, and duikers).¹¹⁰

Ebola hemorrhagic fever is thus a zoonotic disease that often is transmitted to humans by direct contact with infected animal carcasses, which are themselves probably infected from the reservoir animal species that harbor the virus, symptomatically or asymptotically. Since the first recorded human outbreak occurred, many field and laboratory studies have been conducted in attempts to identify Ebola virus reservoir species. Wild animals (vertebrates and invertebrates) were captured in the field, and blood and tissues were used to inoculate Ebola virus-permissive Vero cells. Six field studies, conducted from 1976 to 1995, examined a total of 7000 vertebrates and 30,000 invertebrates, but none was found to harbor Ebola virus.^{90,125} Although small Ebola virus nucleotide sequences and Ebola virus-like nucleocapsids were detected in organs of six mice (*Mus musculus* and *Praomys* spp.) and a shrew (*Sylvisorex ollula*) caught in Central African Republic in 1999,¹²⁵ no conclusions could be drawn as to their reservoir status.

All attempts at experimental inoculation of rodents, bats, birds, reptiles, mollusks, arthropods, and plants have failed, although some bat species belonging to the genera *Epomophorus* and *Tadarida* developed transient viremia lasting nearly 4 weeks.^{166,176} These results did not provide conclusive evidence that bats serve as an Ebola virus reservoir.

Other field collections were conducted during 2002 and 2003 in Gabon and the Republic of Congo, in areas hit by the different outbreaks. A total of 1030 animals were captured, necropsied, and analyzed. The captures and laboratory analyses spanned a period of 4 years. The results showed that three species of fruit bat (*Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*) were asymptotically infected by Ebola virus.^{46,109} Indeed, anti-Ebola virus immunoglobulin (Ig)G was detected in the serum of 16 bats (four *Hypsignathus*, eight *Epomops*, and four *Myonycteris*), but no other animal species, including other bat species, were positive. Likewise, Ebola virus nucleotide sequences were detected in the organs of 13 bats (three *Hypsignathus*, five *Epomops*, and five *Myonycteris*). Sequencing of the amplified fragments confirmed they were specific to Ebola virus. Phylogenetic analysis of the sequences by the Bayesian and maximum parsimony methods showed they belonged to the species *Zaire*. Although the virus itself was not isolated, this work provided the first biologic evidence that some fruit bat species harbor Ebola virus. In addition, these findings were in keeping with certain epidemiologic clues from previous outbreaks and with the transient viremia observed in some bat species after experimental challenge. The distribution of the bat species also matched that of the outbreaks. Recent studies implicate the Egyptian fruit bat (*Rousettus aegyptiacus*) as the reservoir host for Marburg virus. This Egyptian fruit bat is a cave-dwelling species widely distributed across Africa and carries the virus asymptotically.

The most recent Ebola epidemic has added further evidence of the potential role of fruit bats in the transmission of Ebola virus. In Guinea,

the epicenter of the 2014–15 epidemic, large fruit bat colonies (*Eidolon helvum*, *Hypsignathus monstrosus*, *Mops condylurus*) inhabit the Ziama Biosphere Reserve. Bats were commonly found under roofs of houses in the villages. The house where the index case in the 2014–15 epidemic lived was in one of these villages and was very close to a hollow tree that was inhabited by bats. A field mission in southeastern Guinea in April, 2014 investigated human exposure to bats, bushmeat, and captured local wildlife and bats in the village and neighboring forest. Bat hunting in this village was common practice as a food source. Children often caught bats, and the index case reportedly frequently played in the hollow tree inhabited by a bats. The hollow tree had been burned prior to arrival of the investigation team, and no Ebola virus RNA was detected at the site or in trapped animals in the area.¹⁴⁶

In 2009, domestic pigs in the Philippines were discovered to host *Reston ebolavirus*, meaning that they might pose a transmission risk to farm, veterinary, and slaughterhouse workers exposed to infected pigs.^{10,114} In 2011, domestic pigs in China had evidence of *Reston ebolavirus*, and strains were closely related to the *Reston ebolavirus* variant discovered in domestic pigs the Philippines.¹³¹ Pigs have also been experimentally infected with *Zaire ebolavirus* via respiratory exposure and shown to develop lower respiratory tract disease and shed high titers of Ebola virus. In this animal model it was unclear if spread to naïve animals was from virus contaminating the environment with oronasal secretions or via an aerosol route.⁹⁴

Human to Human

Although the first case of human infection in the 2014 epidemic was probably acquired from an animal, all subsequent cases are likely to have arisen from human-to-human transmission. The main route of transmission in this and in previous outbreaks was direct personal contact with blood or body fluids of a person with symptomatic EVD. In contrast to outbreaks occurring in remote rural villages in Africa, epidemics in more urban settings are due to the introduction of a single case in the community, as was the case in the largest Ebola epidemic ever recorded. In the 2014–2015 Ebola epidemic, phylogenetic analyses of Ebola virus from early cases in Guinea were indistinguishable, yet they were distinctly different from an emerging clade of Ebola virus in DRC during the same time period.⁸ Later genetic sequencing from Ebola virus from Conakry suggested three related lineages. Historic outbreaks as well as the most recent outbreak have shown that household exposure is a significant risk factor, especially for those caring for someone ill with Ebola. Of interest, household exposure for children is not as great a risk. This might be because although they lived within the household, young children did not have responsibility for caring for ill family members.^{18,35,73,96}

Cultural practices. Cultural practices played a significant role in the ongoing transmission of Ebola in the 2014 Ebola epidemic. Through contact tracing and exposure risks assessment, it was determined that many individuals' only contact with Ebola was attending a funeral of someone who died of the disease. Titers of Ebola virus are very high at time of death, and risk of transmission is great with direct physical contact with an infected person or their body fluids during the later stages of illness or after death. Contact with the bodies and fluids of persons who have died of Ebola is especially common in West Africa, where family and community members often touch and wash the body of the deceased in preparation for funerals. These cultural practices were shown to be a route of Ebola transmission in the 2014 epidemic. As an example, an investigation of a cluster of cases in a remote village of Guinea, the investigation found that 85 confirmed Ebola cases were linked to one traditional funeral ceremony.^{31,182}

Health care–Associated. Prior to the 2014 Ebola epidemic Ebola transmission to health care workers was rare.¹ Health care workers are especially at risk for acquiring EVD if proper personal protective equipment (PPE) is not available or is not used appropriately. The most recent epidemic impacted health care workers significantly, with many health care workers dying of the disease.¹⁸² Nosocomial transmission to two health care workers at a hospital in the United States highlighted that the potential for transmission is not limited to resource-limited settings.²⁸

Although it was suspected sexual transmission of Ebola virus occurred in cases in the Democratic Republic of the Congo in 1995, the 2014–15

outbreak provided convincing evidence of sexually acquired EVD. Ebola virus is detected in the semen of survivors up to 7 to 9 months after resolution of the acute illness.^{181,33} Cases have been reported of EVD in sexual contacts of survivors who had negative blood Ebola virus PCR and after transmission in the community had been eradicated.^{29,119}

CLINICAL MANIFESTATIONS

Marburg virus and the four Ebola virus species all cause severe, usually fatal hemorrhagic fever, but they differ in terms of the incubation period, clinical severity, and case fatality rate.¹¹⁶

Among the four species of Ebola virus that cause *human* infections, the clinical syndrome may vary significantly, though the majority of all outbreaks in humans are secondary to Zaire Ebola virus, including the 2014–15 outbreak in West Africa. After infection occurs, there is an incubation period ranging from 2 to 21 days (mean, 4–10 days), followed by the onset of fever, malaise, and myalgias. With the abrupt onset of fever, the patient now becomes infectious and capable of spreading the virus. The clinical course then progresses rapidly, followed by multisystem involvement, with severe gastrointestinal symptoms including abdominal pain, nausea, vomiting, and diarrhea leading to severe electrolyte disturbances. Other symptoms include headaches, sore throat, persistent hiccups, and a maculopapular rash. Symptoms rapidly progress to septic shock and resultant multiorgan failure, including renal failure, delirium, severe liver failure, and, in 50% of cases, disseminated intravascular coagulation followed by hemorrhage. Although massive hemorrhage occurs infrequently, it is usually manifested by significant GI bleeding and is typically not the cause of death. Defects in blood coagulation more commonly include mucosal bleeding, bleeding from peripheral IV sites, petechiae, and ecchymoses.^{11,120} In the 2014 outbreak, only 19% of patients reported symptoms of unexplained bleeding as compared to previous reports of 50%.^{43,151}

The incubation period of Marburg virus fever is almost identical to that of Ebola virus fever; clinical onset also is abrupt, starting with fever, chills, headache, and muscle pain. A week later, some patients develop a maculopapular rash, nausea, vomiting, chest pain, abdominal pain, diarrhea, and sore throat. Clinical status deteriorates gradually, with jaundice, delirium, shock, liver failure, massive hemorrhaging, and multiorgan dysfunction.^{23,83,137,159} Although the virus disappears quickly from the bloodstream of survivors, it can persist in the eyes and testicles.^{38,117} Marburg virus was recovered from the semen of one patient some weeks after clinical recovery.

Pediatric Patients and 2014 Outbreak

Pediatric patients have typically represented a minority of all patients presenting with suspected or confirmed Ebola virus. The incubation time is usually reduced relative to adults, and the progression of the disease appears to be faster.¹⁹³ The case fatality rate in children, especially those younger than 5 years, is quite high, though mortality rates for neonates are reportedly 100%.⁹⁶ Major risk factors for infections during the 2014 outbreak in West Africa, such as washing of bodies during ritual burials and direct care of sick relatives, were less likely to occur in children and may partially account for the lower overall incidence of infection in pediatric patients. In some reports children accounted for 10% to 33% of the patients being treated in Ebola Treatment Units (ETUs) (Fig. 187.4).¹⁷⁵ Other authors suggest that there might be underreporting of Ebola virus cases in children as a result of faster progression to death, lower rates of attribution of fever to Ebola, and a lower likelihood of being reported as a contact.⁷³

Similar to adults, there is a wide range of symptoms that occur in children infected with Ebola virus. After an incubation of 2 to 21 days, patients usually develop fever, chills, anorexia, headache, and myalgia. A rash is commonly seen. In contrast to adults, children more often present with fever and are less likely to report specific complaints of pain, dyspnea, dysphagia, and hiccups. Although Ebola is designated as a hemorrhagic virus, significant bleeding or bloody diarrhea is seen in a minority of patients. Gastrointestinal involvement predominates after the initial symptomatology, which may include significant diarrhea, emesis, and abdominal pain. It has been suggested that young children are less likely to be able to report such symptoms, which may distort these differences.⁴⁰

FIG. 187.4 An unidentified little boy, standing outside an Ebola Treatment Unit in Liberia, who was the sole survivor from a family of 12 who died during the Ebola outbreak of 2013–16 in Liberia, Africa. (Photo courtesy Dr. Majid Sidigh.)

Post Ebola Sequelae

Little is understood about how survivors of Ebola virus fare, particularly in regard to long-term sequelae. A “post-Ebola syndrome” has been described and includes prolonged abdominal pain, ocular disease and vision loss, neuropsychiatric issues, significant fatigue, and arthralgias.^{191,152} In a recent study evaluating 166 survivors in Sierra Leone, the most common complaints and diagnoses included arthralgia (77%), fatigue (70%), abdominal pain (54%), headache (52%), anemia (50%), and skin disorders (48%). Ocular complications were noted in 56% of survivors, including uveitis.¹⁶⁹ The psychiatric affects are also significant. Survivors are prone to depression and anxiety, posttraumatic stress disorder, and survivor guilt. Mental health facilities and support in West Africa after the 2014–15 outbreak were limited if available at all. Survivors with mental health issues are shunned and rejected from families.²² The PREVAIL III study in Liberia is an ongoing clinical study that will track more than 1500 Ebola survivors for up to 5 years in an effort to better elucidate the long-term consequences of surviving with Ebola virus.²² The reports of relapses of disease in patients weeks to months after discharge is concerning not only in regard to patient care, but because of the serious implications that prolonged viral persistence may have for transmission and reinfection. Two significant cases include a 43-year-old physician who recovered from EVD and was subsequently found to have severe unilateral uveitis during convalescence. Ebola virus was detected in the patient’s aqueous humor using quantitative RT-PCR, 9 weeks after the clearance of viremia.¹⁷⁹ The second patient was a 39-year-old nurse who had recovered from Ebola virus and had been discharged from the hospital with undetectable Ebola virus RNA in peripheral blood. Nine months after discharge, she developed rapid-onset severe headache, neck pain, photophobia, fever, and vomiting. She was readmitted to the hospital, and lumbar puncture showed high levels of Ebola virus RNA in her cerebrospinal fluid (CSF). The patient was isolated appropriately, and treated with early supportive therapy, as well as antiepileptics, appropriate antibiotics, and GS-5734 (see treatment section, nucleoside analogue). The patient slowly improved and was eventually discharged from the hospital after 52 days of treatment, with

only residual weakness of her left leg as well as left-sided deafness.⁸⁴ Although the cause of post-Ebola syndrome is likely multifactorial, further research and adequate funding is needed to further elucidate the true scope and improved therapies to offer patients.

PATHOLOGY

With the unprecedented 2014–15 Ebola virus outbreak, more information than ever is now available regarding the pathology of Ebola virus infections in humans. In the past, the largest body of data had existed in experimentally infected rodents and nonhuman primates. Still, why some people recover from filovirus fevers and others die remains unclear.

No major difference exists in the pathogenesis of the different filovirus diseases. Studies of *Zaire ebolavirus* show that dendritic cells and macrophages are the initial host targets at the entry site.^{42,63,66} These infected cells then disseminate through the bloodstream and lymphatics to all organs, where they release virions that infect monocytic cells in lymph nodes, spleen, liver, and other organs and tissues.² In the later stages of the disease, the virus also infects other cell types, such as hepatocytes, adrenal cortical cells, and endothelial cells, causing lysis and necrosis.⁶⁵ Lymphocytes do not seem to be infected, but they nonetheless undergo bystander apoptotic lysis.⁶¹

The pathogenetic mechanisms of filovirus infection involve both direct damage to infected cells^{50,130,164,185} and indirect insults through interactions between the virus and the adaptive immune system.^{20,124} By contrast with other viruses, filoviruses can infect and kill a wide variety of cells throughout the body. This apparent lack of target cell specificity may be due to the binding of the viral surface glycoprotein to widely distributed cell surface lectins.¹⁵⁴ Infection of macrophages and dendritic cells can suppress various cellular functions, including the production of proinflammatory mediators such as interferon (IFN)- α , interleukin-1 β , and tumor necrosis factor- α (TNF- α),^{6,16,71} contributing to the suppression of innate antiviral responses and weakening adaptive immune responses. Studies of serial samples from infected nonhuman primates have shown that lymphocytes undergo apoptosis in vivo, probably through the TNF-related apoptosis-inducing ligand (TRAIL) and FAS pathways.^{46,63,61} These findings are compatible with the massive intravascular apoptosis of peripheral monocytic cells observed in patients who died (but not in those who survived) during the 1996 outbreaks in Gabon.⁷ This bystander lymphocyte destruction has been suggested to play a major role both in immunosuppression and in the onset of septic shock observed in nonsurvivors.⁵⁰ Various studies have shown that filovirus infection of endothelial cells causes their lysis and a loss of vascular integrity, leading to disseminated intravascular coagulation, vascular dysfunction, and finally shock.

DIFFERENTIAL DIAGNOSIS

In the clinical setting, Marburg and Ebola virus fevers must be distinguished from other viral hemorrhagic diseases occurring likely simultaneously in Africa, including Lassa fever and yellow fever, as well as from the many bacterial, rickettsial, and protozoal diseases that can cause similar initial signs and symptoms. The absence of jaundice helps eliminate yellow fever and Rift Valley fever. Because of their prevalence in the population in African countries in particular, it is important to rule out and treat malaria and typhoid fever, but it is still important to realize these may be coinfections. For patients seen outside Africa, the travel history is the most important diagnostic sign available to physicians. Imported cases in travelers have occurred, resulting in significant public health consequences,¹⁵ and the increase in global air travel, the rise of tourism in Africa, and the greater dispersion of military troops increases the possibility for importation of filoviruses to non-endemic areas.¹²

DIAGNOSIS

Early laboratory diagnoses of Ebola virus and Marburg virus infection are based on antigen-capture ELISA, RT-PCR, real-time PCR, and virus isolation.^{100,99,101,108,172} These tests are the most accurate tools for diagnosis of acute Ebola virus fever. Later in the course of the disease, or after

recovery, diagnosis relies on IgM-capture ELISA or IgG antibody detection. Interestingly, however, in a significant proportion of patients in whom the disease is fatal, specific antibodies do not develop. These diagnostic tools also may be used for oral fluid specimens obtained from clinical patients.⁵² Quantitative PCR and viral load of Ebola virus has also been used to monitor patients during the recovery phase of and as a predictor of outcome.^{173,30,32,104} During the 2014–2015 Ebola epidemic, the CDC Viral Special Pathogens Branch set up a molecular diagnostic laboratory in Sierra Leone and tested paired blood and oral swab specimens obtained from living patients in the Médecins Sans Frontières Ebola treatment center in Bo, Sierra Leone's second largest city. Testing of the oral swab specimens was consistently less sensitive. As in previous outbreaks, swab specimens for detection of Ebola virus was of limited utility except in severely ill patients or corpses.^{139,52} These recent field laboratories studies also demonstrated that neither delay from collection to testing nor settings without temperature or humidity controls impaired the sensitivity of the RT-PCR assay. The disadvantage of these RT-PCR assays is the requirement for electrical power, laboratory expertise, and training to perform the assays.³⁹ Lateral flow immunoassays are point-of-care assays that are designed for use outside of a formal laboratory setting. These assays are activated when a liquid sample is applied to a membrane that contains a specific antibody and then a second antibody with a colored or fluorescent detector creates a visible change when the target antigen is present. During the 2014 outbreak lateral flow immunoassays were studied at several sites. One that was previously developed by the Naval Medical Research Center for Ebola virus detection was studied at the Liberian Institute for Biomedical Research using clinical samples from patients with suspected Ebola virus infection or oral swabs from deceased individuals as part of the Ebola outbreak response. Ebola virus by RT-PCR and laminar flow immunoassay were compared on 527 samples from patients in Liberia. The Ebola virus laminar flow assay results had greater than 95% accuracy for both plasma and oral swabs when compared with RT-PCR.¹³⁶ Because large quantities of Ebola virus are present in dermal tissue, skin necropsy with immunohistochemical analysis was previously proposed for postmortem diagnostic confirmation; however, in the most recent outbreak, use of oral swabs and testing by RT-PCR or laminar flow assay was implemented.²⁰⁶ These specimens are easy to collect, and formalin fixation renders them safe for transport. Skin biopsy testing is not sufficiently sensitive for early diagnosis, however, and thus should be reserved for dead or dying patients.

Cases have been classified depending on epidemiologic risk category and the patient's clinical manifestations. The first consideration of risk is if the exposure occurred in a country with high rates of transmission, as was the case in West Africa in 2014–15. Next the type of exposure is considered, with the greatest risk being exposure to a patient in the severe stage of the infection or someone who has died of Ebola. Listed next are categories developed by the CDC for exposure risk assessment outside the high-transmission areas:

High risk includes any of the following:

- Percutaneous (e.g., needle stick) or mucous membrane exposure to blood or body fluids (including but not limited to feces, saliva, sweat, urine, vomit, and semen) from a person with Ebola who has symptoms
- Direct contact with a person with Ebola who has symptoms, or the person's body fluids, while not wearing appropriate PPE
- Laboratory processing of blood or body fluids from a person with Ebola who has symptoms while not wearing appropriate PPE or without using standard biosafety precautions
- Providing direct care to a person showing symptoms of Ebola in a household setting

Some risk includes any of the following:

- Being in close contact with a person with Ebola who has symptoms while not wearing appropriate PPE (for example, in households, health care facilities, or community settings)

Low (but not zero) risk includes any of the following:

- Brief direct contact (such as shaking hands) with a person in the early stages of Ebola, while not wearing appropriate PPE. Early signs can include fever, fatigue, or headache
- Brief proximity with a person with Ebola who has symptoms (such as being in the same room, but not in close contact) while not wearing appropriate PPE

- Laboratory processing of blood or body fluids from a person with Ebola who has symptoms while wearing appropriate PPE and using standard biosafety precautions
- Traveling on an airplane with a person with Ebola who has symptoms and having had no identified some-risk or high-risk exposures
- Direct contact with a person with Ebola who has symptoms, or the person's body fluids, while wearing appropriate PPE
- Being in the patient-care area of an Ebola treatment unit
- No identifiable risk includes any of the following:
 - Laboratory processing of Ebola-containing specimens in a Biosafety Level 4 facility
 - Any contact with a person who is not showing symptoms of Ebola, even if the person had potential exposure to Ebola virus
 - Contact with a person with Ebola before the person developed symptoms
 - Any potential exposure to Ebola virus that occurred more than 21 days previously
 - Having been in a country with Ebola cases, but *without* widespread transmission, cases in urban settings with uncertain control measures, or former widespread transmission and now established control measures, and not having had any other exposures
 - Having stayed on or very close to an airplane or ship (for example, to inspect the outside of the ship or plane or to load or unload supplies) during the entire time that the airplane or ship was in a country with widespread transmission or a country with cases in urban settings with uncertain control measures, and having had no direct contact with anyone from the community
 - Having had laboratory-confirmed Ebola and subsequently been determined by public health authorities to no longer be infectious (i.e., Ebola survivors)

A patient under investigation is defined as the following:

- A person with fever and a history of contact with a confirmed or suspected case (i.e., a person with fever, headache, vomiting, loss of appetite, diarrhea, weakness or severe fatigue, abdominal pain, body aches or joint pains, difficulty swallowing, difficulty breathing, and hiccups; and any person having died of unknown causes in a country with high transmission rate).

Laboratory-confirmed cases are defined as the following:

- A case that meets the surveillance case definitions, and the patient has positive test results for Ebola virus antigens, Ebola virus IgG antibodies, or Ebola virus genomic sequences (RT-PCR).

INFECTION CONTROL AND PREVENTION

In the United States, the first step in managing suspected patients was first identifying those patients at risk for infection based on travel and symptom screening. Next, patients were to be placed in isolation until a full assessment and diagnostic testing, if indicated, could be performed. In the United States a tiered approach was developed for hospitals: Tier 1 hospitals identify and isolate patient under investigation. Tier 2 hospitals are Ebola assessment facilities that have the capacity to care for the patient until confirmatory testing is performed. Tier 3 are Ebola treatment centers to care for confirmed cases for the duration of illness. In each of these settings standard, contact, and droplet precautions should be employed. Additional infection control and prevention measures when evaluating patients under investigation or patient confirmed as having Ebola virus disease include the following key components: (1) patient placement in a single room (with a bathroom) with log maintained of all persons entering the room, (2) PPE to be used by health care workers, (3) dedicated or disposable medical equipment, (4) hand hygiene, (5) active monitoring of all personnel for exposure, signs and symptoms, and (6) environmental cleaning and management of waste. The specific type of PPE varies, but the proficiency of use and specific training and practice in donning and doffing PPE is what has been shown to be most important. Active training, including computer simulation and spoken instructions, led to fewer errors with guidance on which PPE to use and how to remove it among health care staff compared to passive training.¹⁸⁰

In countries with high rates of Ebola virus transmission, infection control measures included identifying and isolating patients under investigation for Ebola virus disease, prioritizing protection of both

patients and health care workers, cleaning up safely after caring for patients under investigation, and safe and compassionate care and burials. In these settings PPE may be limited to PVC or rubber boots, gloves, impermeable gown or coveralls, apron to provide maximal protection to the front of the body against contaminated body fluids, face mask to protect nose and mouth, goggles or face shield to protect eyes, and a head cover to protect the head from contamination when removing mask or face shields, but this proved to be effective when used properly.

Management of Filoviruses

Ebola Treatment Unit in Resource-Limited Settings

ETUs became the central point for the diagnosis, isolation, and management of patients suspected or confirmed to have Ebola virus. Although no two ETUs are exactly alike, they all share certain features (Fig. 187.5). Access to the unit is restricted by some sort of barrier, usually a large, gated fence. The ETUs are divided into two large areas, the “hot” or “red” zone and the “cold” or “green” zone. In the cold zone workers can work without any special protection, and office spaces, electrical generating equipment, laundry facilities, chlorinated water production, structures for supplies, laboratory, and pharmacy can be found here. The cold and hot zones are separated by a double fence with sufficient separation to provide protection from contamination, typically 3 meters. In the hot zone there are patient wards and lavatory facilities. The patient wards are usually divided into “suspect” and “confirmed,” with the suspect wards sometimes further divided into “wet” (patients with vomiting and diarrhea) and “dry” (few gastrointestinal symptoms). Some facilities have had special wards for pregnant women and pediatric patients.¹⁷⁴ An isolation fence with a gate separates the suspect and confirmed wards. Within the hot zone there exists provisions for the disposal of contaminated waste, as well as a morgue for deceased patients (Fig. 187.6). A gate near the morgue allows for ambulances and a specially trained team to remove bodies for safe burial. The triage area where patients enter the ETU can reside within the cold zone, but must have an entryway for patients to enter the hot zone directly without passing through, and therefore contaminating, the cold zone. In the triage area there exists a barrier between the health care worker and the patient. Workers don their PPE in the “donning station” which is located in the green zone. PPE is not standardized but usually consists of a body suit, gloves (two or three pair), a hood, goggles, boots, masks, and an apron (Fig. 187.7). Once the PPE has been donned, the worker can enter the hot zone through a gate near the donning station. Once the hot zone is accessed, the workers must use a unidirectional path. First they enter the suspect wards, next the confirmed wards, and then they must remove their PPE, which by this point can be highly contaminated. A “doffing station,” which is partly located in the hot zone and partly in the cold zone, allows the worker to carefully remove the components of the PPE

FIG. 187.5 A video surveillance photo from inside the “hot zone” of an Ebola Treatment Unit in Liberia, Africa, during the 2013–16 Ebola outbreak. Dr. David Hilmer (one of the chapter authors) and colleagues care for a dying woman with suspected Ebola hemorrhagic fever. (Courtesy Dr. Kenneth Marx.)

in a standardized and highly choreographed manner. This is done in coordination with another worker standing in the cold zone, who directs the doffing process and sprays the person exiting the hot zone with chlorinated water as the PPE is taken off. Once the PPE has been removed, the now decontaminated worker will step across into the cold zone.

Biocontainment Units in Developed Countries

With the 2014–2015 Ebola outbreak, a total of 27 cases of EVD were treated in the United States and Europe, in 15 different hospitals in 9 different countries. All patients required close monitoring and aggressive supportive care, including intravenous fluid hydration, correction of significant electrolyte abnormalities, nutritional support, and critical care management for respiratory and renal failure. Seven patients (26%) received invasive mechanical ventilation. Five of the seven patients who received invasive mechanical ventilation also received continuous renal replacement therapy. Five patients died, with an overall 18.5% mortality rate after 28 days of illness.¹⁷⁷ This public health emergency highlighted the need for increased overall preparedness, including the ability to provide high-level care for critically ill patients with serious communicable diseases such as Ebola virus in biocontainment units where staff were not only safe, but trained in the concepts of biocontainment, PPE, and the equipment needed to care for these complex patients.⁹⁰ In resource-rich settings, it may be feasible to build true biocontainment facilities in the hospital setting, as exemplified at the University of Nebraska Medical Center (Omaha), Emory University (Atlanta) and Texas Children's Hospital (Houston). This requires advance planning, adequate space, and institutional support. Key concepts to such a unit include negative air pressure ventilation systems, disinfectant pass-through boxes,

restricted access, cleanable surfaces, laboratory facilities, and the ability to handle and process biohazardous waste¹⁵⁸ (Figs. 187.8 to 187.13). Last, purposeful recruitment of staff is crucial to the success of such a unit, and staff should be a mix with different skill sets. A varied group of nurses and physicians is helpful to have on a team, but having a majority with critical care skills is helpful. Ongoing, quarterly training is required to maintain competency in special skills, including training in PPE, procedures, and unit protocols to ensure the safety of the staff, as well as build the team dynamic, helping them to work together in a high-risk, unfamiliar environment (Figs. 187.14 to 187.16).

Supportive Care

No specific antiviral treatment for filoviral hemorrhagic fevers is licensed.^{14,45} Standard medical treatment relies on symptomatic measures aimed at maintaining hydration, managing severe electrolyte disturbances, reversing cytokine storm and disseminated intravascular coagulation, treating hemorrhage with transfusions, and managing organ failure. In addition, maintaining nutritional status and preventing or curing bacterial and parasitic superinfections are important for management. Appropriate control measures for health care workers and family members to prevent secondary transmission are important to follow. Barrier techniques to prevent direct physical contact with the patient and the patient's secretions and blood, including wearing of protective gowns, gloves, and masks; placing the infected patient in strict isolation; and sterilization or incineration of needles, equipment, and patient excretions are recommended. A manual prepared collaboratively by the CDC and WHO is available and addresses early provisional diagnosis, medical response, and measures to prevent spread of filovirus disease and other viral hemorrhagic fevers within a limited infrastructure that is likely in the African health care setting⁷⁹ (<http://cdc.gov/ncidod/dvrd/spb/mnpages/vhfmanual.htm>).

Treatment of Ebola in Children and Pregnant Women

In developing countries, there is a lack of comprehensive guidelines for care of pregnant women and pediatric patients infected with Ebola virus. One ETU reported the creation of a pediatric ward within the confirmed and suspect zones.^{145,175} Parents who were also patients were allowed to stay with their children in these wards until a discordancy in their status was confirmed, with subsequent separation of the dyad. As for all patients, treatment is mainly supportive. The majority of children are given a full course of malaria treatment, even if testing negative, as most treatment units are located in areas where malaria is endemic. Likewise, broad-spectrum antibiotics are often administered empirically, given the difficulty in distinguishing between the symptoms of Ebola virus and a bacterial process as well as possible translocation of bacteria through the intestinal mucosa while infected with Ebola virus. Zinc is given to those patients with significant diarrhea. Patients are allowed to drink oral rehydration solutions liberally if able. If unable to tolerate oral therapy, intravenous fluids are administered to replace gastrointestinal losses. However, care must be taken not to be overly aggressive with rapid fluid resuscitation, as increased mortality rates have been reported with large fluid boluses in recent studies in children with children in Africa with severe infections, as compared to children in the United Kingdom and United States.^{113,194} Some possible approaches include vital signs, signs of dehydration on physical exam, direct measurement of input and output, and measurement of electrolytes. The use of bedside ultrasound to measure the inferior vena cava diameter has been reported. In the developing world, many children may have underlying malnutrition that predates infection with Ebola virus, and this can affect the immunologic response. Therefore, moderate and severe malnutrition must be addressed early and aggressively. Ready-to-use therapeutic foods (RUTF) and available formulas should be used to treat malnourished patients.

The care of EVD in pregnancy is particularly difficult. There is a high rate of spontaneous abortions, high mortality rate for the mother, and elevated risk of preterm complications, as well as a high risk of transmission to health care workers who are attending a delivery^{77,127} (http://apps.who.int/iris/bitstream/10665/184163/1/WHO_EVD_HSE_PED_15.1_eng.pdf) For women who give birth with active EVD, there are no reports of survival beyond the neonatal period. Intrauterine contents appear to be PCR positive for Ebola virus. As a result, the WHO issued guidelines for the diagnosis and management of Ebola virus in pregnant women⁷⁷ (http://apps.who.int/iris/bitstream/10665/184163/1/WHO_EVD_HSE_PED_15.1_eng.pdf).

Typical pair of isolation rooms

FIG. 187.8 Typical floor plan of a set of two rooms in the eight-bed Pediatric Special Isolation Unit at Texas Children's Hospital West Campus, Houston. It is designed for pediatric biocontainment of fluid-borne and air-borne contagious pathogens, such as Ebola and Marburg viruses, Lassa fever virus, smallpox, monkeypox, Middle East respiratory syndrome, severe acute respiratory syndrome, avian influenza, measles, pneumonic tularemia, and multidrug-resistant tuberculosis. It provides for containment at the level of the room, not at the level of the entire unit. The floor plan includes a safe or "cold" "green zone" secured corridor where parents and other visitors and health care professionals may walk, and a "green" "cold" anteroom for passing of needed materials and supplies and observation. The "yellow zone" is the separate anteroom with specialized negative air flow, for donning and doffing of personal protective equipment and preparation of contaminated trash for exit from the isolation room. The "red zone" or "hot" zone is the isolation room and bathroom for the patient and contains all potentially infectious materials. In addition, each room has a designated nurse substation with large glass window and electronic communications. (Courtesy Dr. Amy Arrington and Texas Children's Hospital.)

FIG. 187.9 The patient room area in the Pediatric Special Isolation Unit at Texas Children's Hospital, Houston. To the far left is the nurse substation patient window with specialized communication technology to limit staff exposure and to facilitate patient care. The top left is the "yellow zone" anteroom doffing-donning glass entry door for easy visibility, and to the right the door to the patient bathroom and the patient care area. All floor surfaces and counter surfaces are smooth, impermeable, and designed for easy cleanup and decontamination. To reduce the stress associated with isolation, age-appropriate toys and distractions are available, and patients are able to communicate with their family via video chat using a special tablet computer. These flexible, dual-purpose patient rooms, when not "activated" and secured for special isolation, may be used for routine pediatric inpatient care. (Courtesy Dr. Amy Arrington and Texas Children's Hospital.)

Because pregnancy may mask some of the symptoms of early Ebola virus, a heightened awareness must be maintained. Pregnant women in endemic areas should be admitted to facilities that have obstetric facilities with proper infection control.³⁶ For those assisting with delivery, full PPE with double gloving and elbow-length gloves is recommended.⁴

FIG. 187.10 "Yellow zone" anteroom doffing-donning area, shared by two patient rooms in the Pediatric Special Isolation Unit at Texas Children's Hospital, Houston. The anteroom has three doors, two providing entrance to each of the patient rooms, and one for entry to and from "green zone" to "yellow zone." In the donning and doffing anteroom, members of the Special Response Team put on or remove personal protective equipment according to a standard procedure. In addition, in the "yellow zone" anteroom waste and trash will be appropriately bagged and sealed prior to removal and transfer to the on-site, in-unit autoclaves. (Courtesy Dr. Amy Arrington and Texas Children's Hospital.)

Experimental Therapies

Phosphorodiamidate Morpholino Oligomers

Administration of positively charged phosphorodiamidate morpholino oligomers (PMOs), delivered with various dosing strategies, protected more than 60% of rhesus monkeys against lethal Zaire Ebola virus challenge and 100% of cynomolgus monkeys against Lake Victoria Marburg virus infection, suggesting PMOs may be useful for treatment.^{14,67} AVI 6002 is a combination of positively charged phosphorodiamidate morpholino

FIG. 187.11 Secure “pass-through window” in the Pediatric Special Isolation Unit allows for safe transfer of needed supplies, small equipment, and patient samples back and forth from clean “green zone” nurse substation to contaminated “red zone” patient care room. Use of the pass-through window reduces the need for patient caregivers to repeatedly don and doff personal protective equipment when transfer of equipment, supplies, or samples is needed. (Courtesy Dr. Amy Arrington and Texas Children’s Hospital.)

FIG. 187.12 On-site, unit-based Biosafety Level 3 Laboratory in the Pediatric Special Isolation Unit at Texas Children’s Hospital, Houston. This laboratory is designed for rapid detection of unusual and usual pathogens that may be needed to diagnose patient illness and also may perform other laboratory monitoring tests. It contains a biosafety hood, specialized air flow, and laboratory autoclave and is staffed by trained laboratory technicians. (Courtesy Dr. Amy Arrington and Texas Children’s Hospital.)

FIG. 187.13 On-site, unit-based autoclave room located in the Special Isolation Unit at Texas Children’s Hospital, Houston. It contains two autoclaves and is staffed by environmental service technicians specially trained in disposal of contaminated waste products. Disposal of the large quantity of contaminated waste and trash produced during care of patients with Ebola hemorrhagic fever is critical to maintain appropriate biocontainment. (Courtesy Dr. Amy Arrington and Texas Children’s Hospital.)

FIG. 187.14 The Special Isolation Unit (SIU) of Texas Children’s Hospital is staffed by a Special Response Team (SRT) consisting of doctors, nurses, respiratory therapists, medical technicians, and environmental services technicians. The SRT members are all trained in biocontainment and management of patients with Ebola hemorrhagic fever and other airborne and fluid-borne contagious diseases. The SRT has quarterly in-service didactic sessions, review of donning and doffing procedures, review of laboratory procedures, and simulation sessions of patient care scenarios. Shown here is one such simulation in the SIU. A health care worker, in full personal protective equipment, is performing a laboratory test in the patient care area during a patient simulation session, while Dr. Amy Arrington, Pediatric SIU Medical Director, and other SRT members provide oversight of the simulation session through the observational window in the nurses’ anteroom area. (Courtesy Dr. Amy Arrington and Texas Children’s Hospital.)

oligomers designed to target mRNA sequences of VP24 and VP35 in Ebola virus. AVI-6002 was administered intravenously to rhesus macaques 30 to 60 minutes after Ebola virus exposure at varying doses for up to 14 days. Results of this study demonstrated that 60% of macaques given doses of 28 mg/kg and 40 mg/kg survived with 100 times greater suppression of mean viral load at the peak of plasma viremia compared to control animals.¹⁸⁸ Phase I safety trials have shown AVI 6002 to be well tolerated in healthy adult subjects.

Nucleoside/Nucleotide Viral Polymerase Inhibitors

Brincidofovir is a nucleotide analogue and conjugate of cidofovir originally studied as a treatment for double-stranded DNA viruses. Its mechanism of action in RNA viruses such as Ebola virus is not well understood, but it has been found to inhibit *in vitro* infection of Ebola virus in multiple human cell lines.¹²¹ Oral brincidofovir was administered to four patients in Liberia with laboratory-confirmed EVD in a single-arm, phase 2 trial; all four patients died.³⁷

Favipiravir is a RNA polymerase inhibitor that has shown strong antiviral efficacy against lethal doses of Ebola virus in mice.¹⁶¹ From a

clinical research standpoint, favipiravir is currently the most advanced of the small molecules and is currently in phase 3 clinical trials.¹⁵⁵

BCX4430 is an adenosine nucleoside analogue, designed to inhibit viral RNA polymerase activity indirectly through non-obligate RNA chain termination, and has been shown to provide complete protection to cynomolgus macaques from Marburg virus infection when administered as late as 48 hours after infection.¹⁸⁹ Phase 1 clinical trials of this drug are currently ongoing in healthy subjects.

GS-5734 is the newest small molecule to be developed against filoviruses and has shown several important findings. In a macaque monkey model, a 10 mg/kg loading dose of GS-5734 was administered 3 days after infection with Ebola virus followed by daily maintenance dosing for 12 days with 3 mg/kg, resulting in a 100% survival rate. Additionally, intravenous administration of GS-5734 to nonhuman primates resulted in persistent GS-5734 levels in peripheral blood mononuclear cells and distribution to sanctuary sites for viral replication including testes, eyes, and brain, suggesting that the drug may be usefully for postexposure prophylaxis as well as post-Ebola syndrome.¹⁸⁷ The drug has been used in an individual suffering from postexposure relapse resulting in meningoencephalitis 9 months after discharge from the initial hospital stay.⁸⁴

FIG. 187.15 Personal protective equipment (PPE) is an important part of staff safety when caring for patients with Ebola hemorrhagic fever or other highly contagious diseases. Shown here are doctors on the Special Response Team for the Pediatric Special Isolation Unit at Texas Children's Hospital, Houston, during a donning and doffing practice session. The PPE includes first layer as hospital scrubs for clothing and plastic clogs as shoes, a battery-powered air purifying respirator with face mask on the head and neck, hooded liquid-repellent one-piece coverall that zips in the front, isolation gown/apron over coverall that ties in the back, hospital shoe covers over Crocs, which are then covered by water-resistant plastic booties, and three pairs of gloves. PPE is donned and doffed according to a specific checklist of instructions in the anteroom area before entering and after leaving the patient care isolation room. Shown here in the photo are two of the chapter authors, Dr. Judith Campbell (second from right) and Dr. Gail Harrison (far right), and Dr. Maria Carolina Gazzaneo (far left) and Dr. Regina Okhuysen-Crawley (second from left), who are all members of the Special Isolation Unit Special Response Team. (Courtesy Dr. Amy Arrington.)

FIG. 187.16 The United States Agency for International Development (USAID) Emergency Isolation Smart Pod set up at EWA Hospital, Monrovia, Liberia, in September 2017. These modular, deployable, portable isolation pods are used as a mobile hospital unit for physicians and technicians to evaluate and care for Ebola patients during their acute illness and after recovery for evaluation of complications. They contain a water sanitation system, drug and supply tracking system, laboratory, and patient isolation beds. They can be shipped by air, land, or sea directly to remote destinations and can be assembled in 5 to 10 minutes by a team of four. (Courtesy Dr. David Hilmers; www.bcm.edu/global-initiatives/innovation-center/emergency-smart-pod.)

Immunotherapeutics

Convalescent plasma has been used for treatment of filovirus infection, but its efficacy has not been proved in randomized clinical trials. In a study conducted during the 1995 Kikwit Ebola epidemic, seven of eight patients who received blood collected from convalescent donors recovered, warranting a thorough evaluation of passive immune therapy.^{88,126} One person infected by *Sudan ebolavirus* after a laboratory accident survived

after receiving plasma from *Zaire ebolavirus* survivors. In the 2014–15 EVD outbreak, several clinical trials evaluating convalescent plasma were conducted in three separate studies.¹⁷⁸ Only the Ebola-Tx trial in Guinea enrolled a sufficient number of patients ($n = 102$); the Ebola-CP trial in Sierra Leone and the EVD001 trial in Liberia both enrolled a small number of subjects ($n = 4$ and $n = 5$, respectively). Data available from these studies showed no severe adverse reactions to convalescent plasma, with no efficacy data yet available. Two patients in the 2014–15 EVD outbreak who were cared for in the United States (Nebraska Biocontainment Unit and Emory University Hospital Serious Communicable Diseases Unit) both received convalescent plasma in addition to an investigational therapeutic drug, TKM-100802, and supportive care. Both critically ill patients recovered completely,⁹⁸ although the role convalescent plasma played in their recovery is unknown. In past studies using convalescent plasma as a treatment in other viral infections including avian influenza, Middle East respiratory syndrome, and hemorrhagic fevers including Lassa and Marburg, results have been conflicting.^{98,178,147}

Hyperimmunoglobulin from horses protected baboons in experimental studies.¹²² Goat immunoglobulin has been tested in laboratory animals and also was given to laboratory researchers suspected of being infected by Ebola virus¹⁰²; one researcher with highly probable infection made a full recovery. Studies have investigated the potential therapeutic utility of a variety of monoclonal antibody preparations for treatment and postexposure prophylaxis of Ebola virus infection.^{24,168} Mouse and human chimeric monoclonal antibodies active against Ebola virus and produced in Chinese hamster ovary and in whole plant cells have been shown to successfully protect rhesus monkeys against lethal viral challenge. Fucose-free monoclonal antibody against Ebola virus has also been found effective in preclinical trials.²⁰⁷

In addition to antibody-based strategies, preclinical development of a variety of antiviral drug strategies for treatment of filovirus infection is in progress. Compound library screening in vitro, with small molecules, and in silicon structure-based drug design are being explored to treat filovirus infection.^{67,132,153} Administration of recombinant nematode anticoagulant protein c2 (rNAPc2), a potent inhibitor of tissue factor-initiated blood coagulation, attenuated proinflammatory and coagulopathic responses and prolonged the survival of macaques that had received a lethal inoculum of Ebola virus.⁶²

ZMapp is an experimental drug composed of three different chimeric humanized monoclonal antibodies that bind specifically to the Ebola surface glycoprotein. In a rhesus macaque model, 100% of these animals survived when ZMapp was administered up to 5 days post-challenge with Ebola virus. Additionally, after ZMapp administration, advanced disease including elevated liver enzymes, mucosal hemorrhages, and generalized petechiae could be reversed, leading to full recovery in these animals.¹⁴³ The recent Partnership for Research on Ebola Virus in Liberia II (PREVAIL II) study was a randomized, controlled trial evaluating ZMapp in patients who had been diagnosed with Zaire Ebola virus during the 2014–15 outbreak in Liberia, Sierra Leone, or Guinea. The study enrolled 72 patients and compared ZMapp to the standard of care: providing fluids, balancing electrolytes, and maintaining blood pressure and oxygen support. Twenty-one of the 72 patients died, a case fatality rate of 29%. Thirteen of the 35 patients (37%) who received only standard care died, while eight of the 36 people (22%) who received ZMapp plus standard care died. The study found ZMapp to be safe and well tolerated; however, because of lack of power due to the small sample size, the study was unable to show statistical significance and determine definitively whether it is a better treatment for Ebola virus disease (EVD) than the best available standard of care alone.¹⁴¹

Vaccine Therapies for Ebola Virus

A variety of vaccine platforms, including DNA vaccines, recombinant replication-deficient adenovirus serotype 5 vector vaccines, recombinant human parainfluenza virus 3, vesicular stomatitis virus-based vaccines, and virus-like particle vaccines, have been investigated and shown to be effective against filovirus infection in animal models.^{20,41,58,92,138,150,163} Successful preclinical developments suggest that studies on the safety and efficacy of a filovirus vaccine for human use may be possible.^{92,150}

Several candidate vaccines against Ebola virus are effective in guinea pigs but less so in macaques.^{64,163} Experimental vaccines in the past

had been based on viral particles inactivated by heat, formalin, or γ -irradiation¹¹²; plasmids coding for the Ebola virus glycoprotein (GP) or nucleoprotein (NP),²⁰³ recombinant GP-expressing Venezuelan equine encephalitis virus,¹⁴² or variola virus; and Ebola virus particles encapsulated in liposomes.¹⁴⁴ In contrast, a vaccine candidate based on three injections of GP-encoding DNA given 4 weeks apart, followed by a booster with recombinant inactivated GP expressing adenovirus, protected macaques from infectious challenge 1 week later.¹⁶⁵ However, the small inoculum used to challenge the macaques (six plaque-forming units [PFU]), together with the lengthy immunization protocol, renders this candidate vaccine impractical.

With the 2014 Ebola virus outbreak in West Africa leading to an unprecedented loss of human lives, heightened awareness on vaccine development led to new advances, including several potential candidate vaccines showing protection against Ebola virus in both animal and human subjects. The first of these is vesicular stomatitis virus (VSV)-EBOV, also known as rVSV-ZEBOV, a recombinant live-attenuated VSV-based vaccine developed against Ebola virus and currently is the first vaccine with reported efficacy against Ebola virus infections in humans in phase 3 clinical trials. This vaccine was shown to completely protect macaques against lethal challenge with the West African Ebola virus-Makona strain with a single dose.¹¹⁸ This vaccine as been used as postexposure prophylaxis as well following a needle-stick injury in a US physician caring for patients in an Ebola treatment center in Sierra Leone. Forty-three hours postexposure, rVSV-ZEBOV was administered to the patient evacuated to the US for treatment.¹⁰³ This patient developed a postvaccine febrile syndrome beginning 12 hours after vaccination, which was self-limited and associated with the brief detection of recombinant vesicular stomatitis vaccine virus in the blood. Strong innate and Ebola-specific adaptive immune responses were detected postvaccination, with no evidence of Ebola virus infection.¹⁰³

A large study was conducted in Guinea using the viral stomatitis vaccine (rVSV-ZEBOV) that included 7651 people who had either been in contact with a patient with known Ebola virus or were a contact of a direct contact.⁸² However, children and pregnant or lactating women were excluded. The patients were divided into two groups; one group received the vaccination immediately after randomization, and the other was given the vaccination 21 days after randomization. None of the 2014 patients in the first group became infected with Ebola, and 16 of the second group of 1930 became infected. Thus, the vaccine was considered 100% effective in those immediately vaccinated and 75.1% overall in this trial. Two other vaccines are currently in phase 3 development. The durability of these vaccines remains to be studied, and there is an urgent need for a vaccine that can be administered to children and pregnant or lactating women.⁴⁸

Other vaccine candidates with promising results include a recombinant adenovirus of various serotypes. A study in 2016 evaluated the reactogenicity and immunogenicity of immunization schedules using two novel candidate Ebola vaccines—an adenovirus type 26 vector vaccine encoding Ebola glycoprotein (Ad26.ZEBOV), and a modified vaccinia Ankara (MVA) vector vaccine, which is an attenuated vaccine of a poxvirus. This vector vaccine encodes glycoproteins from Ebola virus, Sudan virus, Marburg virus, and Tai Forest virus nucleoprotein (MVA-BN-Filo). Vaccines were administered to healthy adult volunteers in the United Kingdom in a Phase I trial. In the randomized groups, 28 of 29 Ad26.ZEBOV recipients and 7 of 30 MVA-BN-Filo recipients had detectable Ebola glycoprotein-specific IgG 28 days after primary immunization. All vaccine recipients had specific IgG detectable at 8-month follow-up. Within randomized groups, at least 86% of vaccine recipients showed Ebola-specific T-cell responses.¹²³ These vaccines are now being further evaluated in Phase II and III studies. In recent studies, recombinant adenovirus (Ad5)-vectored vaccine expressing the Makona Ebola virus glycoprotein (MakGP) was shown to elicit specific B- and T-cell immunity in cynomolgus macaques and conferred 100% protection when these animals were challenged 4 weeks after immunization.²⁰¹

Virus-like particles have shown promise and protect small laboratory animals and nonhuman primates against lethal challenge by Ebola or Marburg viruses.²⁰⁵ Also, a vaccine system based on recombinant vesicular stomatitis virus that expresses filovirus glycoprotein in place of the vesicular stomatitis virus glycoprotein has shown protection against

infection with Marburg and Ebola virus.^{58,59,69,163} Protection of nonhuman primates against Ebola virus infection by both parenteral and aerosol route challenges also has been documented by vaccination with a single complex adenovirus vector vaccine.^{19,138}

CONCLUSION

Filoviruses remain a threat to mankind, but important advances were made following the 2014–15 Ebola outbreak in West Africa. Advances included vaccine development and novel drug therapies, and several Phase III drug trials are underway. We have yet to truly understand the effects of Ebola on long-term survivors, but data showing Ebola virus RNA present in semen and CSF samples of survivors up to 9 months after infection is concerning.^{84,162} Perhaps one of the most important lessons learned from the 2014–15 Ebola outbreak was how to be more prepared both locally and globally for the next one. It is critical to strengthen the medical infrastructure in developing countries where outbreaks are most likely to occur. This includes improvement in staffing and training of medical personnel at the local and national level, reporting of suspected cases, and public education. Critical lessons were learned in how we respond to public health emergencies and the need for improved infection control, isolation of highly infectious patients, and the ability to care for them in specialized units. Being prepared for the next outbreak is critical for preventing a catastrophic epidemic, both locally and abroad. The world is vulnerable to global epidemics as never before, and constant surveillance and preparedness are required on all of our parts.

SUBSECTION X Coronaviridae and Toroviridae

188

Human Coronaviruses, Including Middle East Respiratory Syndrome Coronavirus

Janet A. Englund • Yae-Jean Kim • Kenneth McIntosh

The family Coronaviridae contains two subfamilies, Coronavirinae and Torovirinae. The subfamily Coronavirinae is currently divided into four genera, the alpha-, beta-, gamma-, and deltacoronaviruses; the human coronaviruses (HCoVs) belong in the first two of these. Until recently, HCoVs were considered to cause upper respiratory tract illness and possibly also some undetermined fraction of viral diarrhea. In 2002, a new coronavirus, the SARS coronavirus (SARS-CoV), was found to be the cause of an acute, severe, frequently fatal respiratory disease with prominent systemic symptoms: severe acute respiratory syndrome, or SARS. In 2012, another highly pathogenic coronavirus, the Middle East Respiratory Syndrome coronavirus (MERS-CoV), appeared in Saudi Arabia and neighboring countries.^{41,198} This virus, with a high case-fatality rate and the ability to spread in families and among patients and caregivers in hospitals, is in at least some instances contracted from camels with respiratory disease.¹⁰ The origin of this virus, as with SARS-CoV, may also have been in bats.⁵ In retrospect, the emergence of SARS and MERS-CoV is consistent with what was already known about coronaviruses: these viruses are widespread pathogens in the animal kingdom, evolving rapidly through mutation and recombination, and with a capacity for jumping species barriers.⁸⁷ Coronaviruses cause a wide variety of important diseases in animals, including infectious bronchitis and nephrosis in chickens; gastroenteritis and encephalitis in young piglets; enteritis in turkeys, dogs, and calves; hepatitis and encephalitis in mice; pneumonitis and sialodacryoadenitis in rats; infectious peritonitis in cats; and pneumonia and hepatitis in whales. Multiple strains of unknown pathogenicity have been recovered from numerous species of bats.¹⁸⁹

BACKGROUND

Since the first report of HCoV isolation in 1965,¹⁷⁰ the HCoV group has been repeatedly confirmed to be an important and frequent cause of the common cold and a likely cause of more serious respiratory tract infections in the elderly.^{52,53,64,183} They also have been implicated as contributors to lower respiratory tract infections in children and adults. The first HCoV was cultivated by Tyrrell and Bynoe at the Common Cold Unit in Salisbury, England, with the use of human embryonic tracheal and nasal epithelial mucosal organ cultures.¹⁷⁰ These investigators

were able to produce colds regularly in volunteers inoculated with organ culture fluid from the first and later passages of an agent, B814, obtained from a boy with a cold.¹⁶ Working independently, Hamre and Procknow in 1966 described the isolation of five viruses, including the prototype strain HCoV-229E, in primary human embryonic kidney cell cultures.⁶⁸ Four of these agents were obtained from medical students with upper respiratory tract illnesses and one from a healthy student. The growth of six additional HCoVs, including the second human prototype HCoV-OC43, was reported in 1967 by McIntosh and associates, who used human embryonic tracheal organ cultures inoculated with secretions from adults with upper respiratory tract infections.^{105,107}

The relationship of HCoVs to similar agents known to infect animals soon became evident. By electron microscopy, 229E and B814 were demonstrated to be morphologically identical to each other as well as to avian infectious bronchitis virus.² Subsequently, mouse hepatitis virus was demonstrated to be very similar morphologically and to be antigenically related to HCoV-OC43.^{105,109} Shortly thereafter, these and similar agents were given the name “coronaviruses” owing to the crownlike appearance of their surface projections on electron microscopy.¹⁶⁹

Poor growth and a lack of cytopathic effect in cell culture were, until recently, major deterrents to research on HCoV. With the development of molecular diagnostic techniques including the polymerase chain reaction (PCR), and following the emergence of SARS-CoV^{45,84,135} and, in 2012, MERS-CoV,^{10,41} the field of coronavirology has developed widely and rapidly. Two additional community-acquired respiratory coronaviruses were discovered in the wake of the SARS epidemic: HCoV-NL63 in 2004,^{49,55,175} and HCoV-HKU1 in 2005.^{90,188} These two virus species joined HCoV-229E and HCoV-OC43 as common, endemic respiratory viruses with worldwide distribution and similar, although probably not identical, mild-to-moderate pathogenicity in normal human hosts. In this chapter, these four HCoVs are referred to as “community-acquired respiratory coronaviruses” to distinguish them from SARS-CoV and MERS-CoV.

VIROLOGY

Coronaviruses are medium to large (80–220 nm), pleomorphic, spherical or elliptical enveloped RNA viruses with widely spaced, petal-shaped,

20-nm-long surface projections giving the virus the appearance of a solar corona¹⁰⁴ (Fig. 188.1). They are labile to heat, lipid solvents, and acid pH. The genomes of multiple coronaviruses have been sequenced completely, including those of HCoV-229E, OC43, NL63, HKU1, MERS-CoV, and multiple strains of the SARS-CoV.^{38,55,65,71,144,175,181,182,188} The genome and its surrounding capsid are arranged in helical symmetry and enclosed within a lipoprotein envelope.

Within the coronavirus particle, a nucleoprotein (N) surrounds the RNA genome, and together they appear as a coiled tubular helix within the bilayer lipid-containing envelope. The envelope contains two or three glycoproteins: (1) a matrix protein M, which is embedded in the envelope; (2) a surface component S, which is the structural protein of the petal-shaped spikes and the target of neutralizing antibody; and (3) a hemagglutinin esterase HE, which is found in several of the betacoronaviruses, including OC43 and HKU1, and contains sequences closely related to influenza C hemagglutinin. The four respiratory HCoV species plus the SARS-CoV and MERS-CoV, along with several other mammalian coronaviruses, have been placed in the alphacoronavirus genus (229E and NL63) or the betacoronavirus genus (OC43, HKU1, SARS-CoV, and MERS-CoV) (Box 188.1); avian infectious bronchitis virus and several other coronaviruses have been placed in the gammacoronavirus genus, and several recently discovered avian coronaviruses in the deltacoronavirus genus.¹⁸⁷

Coronaviruses contain a positive-sense, single-stranded RNA genome of molecular weight 26 to 31 kilobases, the largest of any RNA virus

group.⁸⁷ In coronavirus replication, all processes take place in the cytoplasm. In the first step, the virus attaches to the cell membrane by using its HE or S protein in the petal-shaped spike. HCoV-229E uses aminopeptidase N (CD-13) as a cellular receptor,¹⁹⁵ both the SARS-CoV and NL63 use angiotensin-converting enzyme 2,^{72,93} and MERS-CoV uses dipeptidyl-peptidase 4 (CD26),¹⁴⁵ whereas the receptor for HCoV-OC43 still has not been identified definitively. Penetration occurs as a result of S protein-mediated fusion of the viral envelope with the plasma membrane. The large viral replicase gene, which occupies two-thirds of the genome, then codes for a large polypeptide. This polypeptide is cleaved into 15 or 16 nonstructural proteins by two or three virally encoded proteases, and a replication complex is formed. Within this complex, an RNA-dependent RNA polymerase initiates the transcription of subgenomic mRNAs through negative-stranded intermediaries. The mRNA molecules, as in other members of the virus order *Nidovirales*, form a nested set, with the sequences of the first open reading frame at the 5' end (after a leader sequence) containing the coding region and subsequent sequences through to the polyadenylated 3' end being untranslated.¹³² Virions then are assembled by budding into cytoplasmic vesicles in the rough endoplasmic reticulum and Golgi region. Virus particles are released by cell lysis or fusion of post-Golgi, virion-containing vesicles with the plasma membrane.

EPIDEMIOLOGY OF COMMUNITY-ACQUIRED RESPIRATORY CORONAVIRUSES

Early epidemiologic surveys of HCoV infections were carried out by serologic methods of complement fixation, hemagglutination inhibition, and enzyme immunoassays, with 229E or OC43 viruses as antigens.^{24,43,83,99,110} More recently, epidemiologic surveys of 229E, OC43, NL63, and/or HKU1 infection have been based on PCR of respiratory tract samples.^{50,86,95,96,102,127,162,172,190}

Recent epidemiologic studies of enteric HCoVs have been based on PCR detection in stool and respiratory samples obtained simultaneously and are described in the section on clinical manifestations of enteric HCoVs. The epidemiology of SARS-CoV and MERS-CoV is described in the following sections.

Geographic Prevalence

Community-acquired respiratory coronavirus infections occur worldwide. Seroprevalence studies using 229E and OC43 antigens have been conducted in the United States, Europe, Brazil, and Iraq.^{17,25,69,70,80,81,110} With enzyme-linked immunosorbent assay (ELISA), antibody prevalence in adults from all areas where they have been examined approaches 90% to 100%. All four of the community-acquired human coronaviruses have been identified frequently using PCR analysis wherever they have been sought.^{50,86,95,96,102,127,162,172,190}

Seasonal Incidence and Annual Recycling Pattern

Although HCoV infection may occur at any time of the year (Fig. 188.2), the highest rates in temperate climates are seen in midwinter to early spring. The irregular year-to-year pattern described for OC43 and 229E, namely, that individual species predominate for 1 or more years, followed by 1 or more years of lower activity,^{80,81,117,118} appears also to hold for NL63 and HKU1.^{39,142,167,174} More sensitive molecular assays using multiplex PCR have provided more insight into these patterns, confirming earlier reports that one of the four known HCoV species may be the predominant HCoV in a particular area during a particular season, with all four types circulating simultaneously in many years.⁸⁶ Evaluation of community-acquired respiratory coronavirus epidemiology must include tests that are sensitive for all four species.⁸⁶ Because of unpredictable variability, studies carried out over relatively short periods, such as 6 months or even 1 year, are likely to yield misleading results regarding prevalence and incidence. The experience of one laboratory over 4 successive years where symptomatic children were sampled in outpatient and hospital settings is shown in Fig. 188.2.

During outbreaks, specific coronavirus types may be responsible for a large fraction of respiratory tract infections. At the University of Chicago in 1966 and 1967, 229E was associated with a significant outbreak in medical students; 66 (35%) of 191 sampled students were infected.⁶⁷

FIG. 188.2 Distribution of human coronavirus types in respiratory specimens from symptomatic inpatient and outpatient pediatric patients over 4 years at Seattle Children's Hospital using a commercial rapid multiplex polymerase chain reaction (FilmArray, Biofire Diagnostics). This demonstrates concurrent circulation of all four types of human coronavirus (HCoV) during winter months, with predominance of HCoV-OC43 in three seasons and HCoV-229E in another. (Unpublished data courtesy J. Stapp, Seattle Children's Hospital Microbiology Laboratory.)

In Tecumseh, Michigan, a large 229E outbreak in 1967 affected 68% of 38 families and 34% of 159 individuals tested. Distinct outbreaks also can occur in hospitalized infants; at National Jewish Hospital in Denver, 16 of 20 hospitalized asthmatic infants were infected with HCoV-OC43 in December 1968,¹⁰⁸ and smaller outbreaks have been seen in neonatal intensive care units with OC43,¹⁶¹ 229E,⁵⁸ and NL63.⁴⁹

Ratio of Clinical to Subclinical Illness

Although B814, 229E and OC43 clearly caused symptomatic upper respiratory tract disease in adult volunteers, asymptomatic infections were also seen in these volunteer studies. Early surveys of 229E and OC43 that identified infection in infants and children by a rise in antibody indicated that at least 50% of infections were subclinical.^{80,81,110} In contrast, in the Denver children hospitalized with atopic asthma, 19 were infected with either 229E or OC43 and 17 were symptomatic.¹⁰⁸ A 2-year prospective PCR-based study of respiratory illness in more than 600 rural Alaskan children demonstrated similar rates of coronavirus infection in hospitalized children and community controls.¹⁵⁹ Other surveys of HCoVs in both symptomatic and asymptomatic children using detection by PCR have shown almost identical rates of positivity, indicating that in otherwise normal children, community-acquired respiratory coronaviruses may be of low pathogenicity or are shed for prolonged periods.^{15,39,85,142}

The importance of coronavirus in severely immunocompromised patients, such as hematopoietic stem cell transplant (HSCT) patients, has been investigated. In a 2-year prospective study conducted in HSCT recipients of all ages who were sampled weekly before and for 100 days after transplantation, the rates of detection of any of the four species of community-acquired respiratory HCoV in symptomatic versus asymptomatic patients were similar.¹¹⁶ Of note, the duration of shedding of coronaviruses in immunocompromised patients varied from less than 2 weeks (35%) to more than 10 weeks (17%).

Age Specificity of Infection

The first infection with all four HCoVs takes place during childhood, probably during the first 6 years of life.²⁰⁰ Antibody to the HCoVs appears in early childhood, with a tendency for antibody to OC43 and NL63 to appear earlier and more frequently than antibody to 229E and HKU1.⁴³ Prevalence increases rapidly with age. Asymptomatic and symptomatic infection occurs at all ages, including in the elderly. In the Tecumseh families studied during a community-wide 229E epidemic in 1967, only 3 of 54 infections occurred in children younger than 4

years. The attack rate then rose to a peak of 14% in individuals 15 to 29 years of age and subsequently fell with increasing age.²⁵ The results were different in an outbreak of HCoV-OC43 infection. With this virus, the highest rate, 29%, occurred in children 4 years of age or younger, and rates decreased very little even into adult years, when the incidence was 22%.¹¹⁸

Prospective studies during the first year of life of viruses found by PCR in nasopharyngeal samples obtained during acute respiratory symptoms have found coronaviruses, including OC43, 229E, NL63, and HKU1, in 6% to 16% of episodes.^{85,91,148,177} In a birth cohort study that included samples obtained from asymptomatic as well as symptomatic infants, the proportions in the two groups were not significantly different (4.4% in asymptomatic infants vs. 5.5% in symptomatic infants).⁸⁵ In a prospective study of symptomatic children younger than 2 years attending daycare, coronavirus was detected as a sole pathogen in only 4% of upper respiratory tract illnesses but in an additional 11% of illnesses when more than one virus was present.⁵¹ In the same study, the incidence of coronavirus detection by age cohort decreased from a rate of 0.6 infection per child-year for children observed beginning at 0 to 6 months of age to 0.5 infection per child-year for those observed from 7 to 12 months of age and further to 0.2 for those observed from 1 to 2 years of age. Similarly, a longitudinal study among 26 households with children in Utah demonstrated higher (although not necessarily significantly higher) rates of symptomatic disease associated with all four types of HCoV in children ages 0 to 4 years, with relatively similar rates in older children and adults.²² Several studies have emphasized the importance of coronavirus infection in the elderly, particularly in individuals in chronic care facilities and those with underlying cardiopulmonary disease.^{53,60,126}

Transmission

Human volunteers can be infected readily by nose drops containing OC43 or 229E, and a typical cold develops 2 to 3 days later. Natural infections are therefore assumed to occur through the respiratory route. Nosocomial transmission of coronavirus respiratory tract infection has been reported. One study took place in a neonatal intensive care unit, where prospective surveillance by immunofluorescence testing of nasal aspirates performed for 15 months detected 10 infections with coronavirus OC43, all of them nosocomially acquired.¹⁶¹ All infants had apnea, bradycardia, or abdominal distention, or a combination of these pathologic effects, at the time of infection. Another study using PCR analysis for HCoV-229E found three outbreaks occurred in 1 year involving 28% of neonates (43 of 152, most of whom were symptomatic) and 52% of staff members (most of whom were asymptomatic).⁵⁹ The mode of transmission was not demonstrated in either study.

INFECTION AND IMMUNITY

Pathogenesis, Incubation Period, and Serologic Response

In healthy adults, community-acquired respiratory HCoVs seem to replicate only in the upper respiratory tract and to produce little direct cytopathologic effect. In immunocompromised adults, HCoV has been detected in bronchoalveolar lavage fluid,^{60,116} indicating potential replication in the lower airway. In human embryonic tracheal organ culture, a decline in ciliary activity after serial passage was the only cytopathic effect observed.^{107,170} Very similar events appear to take place in vivo. Electron microscopy of nasal epithelial biopsy specimens from a young girl with chronic rhinitis and bronchitis showed preservation of cellular structures and cilia despite replication of coronavirus particles.¹

OC43 and 229E have been detected in nasopharyngeal cells,¹¹¹ and 229E virus titers from 10 to more than 1000 TCID₅₀ (median tissue culture infective dose) were found for a week or more in nasopharyngeal washings.¹²² Bende and associates studied the course of 229E colds in 24 volunteers and delineated the typical signs, symptoms, and virus shedding patterns; eight volunteers were asymptomatic.¹³ The incubation period of HCoV colds is, on average, 2 days, and they usually last approximately 1 week.¹⁶ In small infants, virus may be detectable in respiratory secretions for 3 weeks and longer.¹⁴⁸ Recovery is likely to be dependent on cell-mediated immunity. Infections in immunocompromised subjects may be associated with severe and prolonged

disease,^{7,54,136} although prospective studies have identified asymptomatic infections and prolonged shedding in severely immunocompromised hosts such as bone marrow transplant patients.¹¹⁶ More studies have been devoted to the pathogenesis of SARS¹³⁷ and MERS.

Reinfection

Evidence from human volunteer experiments demonstrates that postinfection immunity can be strain specific. Reed infected volunteers with one of several 229E-like viruses. She found that immunity to homotypic challenge endured for at least 1 year but that immunity to heterotypic HCoV-229E strains in these same volunteers was much lower.¹⁴⁷ IgA antibody may play an important protective role.²³

CLINICAL MANIFESTATIONS OF RESPIRATORY TRACT INFECTIONS

Common Cold and Other Upper Respiratory Tract Illnesses

A significant association of HCoVs 229E and OC43 with respiratory tract illnesses—most of them coldlike—was demonstrated in early prospective serologic studies of adolescents and young adults. In the Chicago medical students described earlier, HCoV-229E attack rates were 31% during “illness periods” and only 9% in matched “wellness periods” ($P < .001$); the illnesses did not differ significantly from undifferentiated acute respiratory tract infections caused by respiratory syncytial virus, parainfluenza viruses, or rhinoviruses.⁶⁷ Similarly, respiratory disease, including pneumonia, was significantly associated with OC43 seroconversion by complement fixation in military recruits at Parris Island and Camp Lejeune in 1971.¹⁸⁴

Symptoms in the adolescents and adults in the two investigations cited earlier were much like those in human volunteers inoculated with HCoV.^{13,16,23,24,147} Infected volunteers contracted typical common colds, with perhaps more rhinorrhea than in rhinovirus colds. Sore throat, cough, malaise, and headache were noted in approximately 50% of volunteers; 20% had fever.

The proportion of total respiratory tract disease or colds attributable to community-acquired respiratory HCoVs varies by season, from year to year, as well as the methodology used. Most serologic surveys have concluded that approximately 8% to 10% of all colds are associated with coronavirus infection.¹⁰¹ A well-controlled study in the Netherlands used PCR for 229E and OC43 to estimate the contribution of coronaviruses to illness at all ages leading to a visit to general practitioners. Coronaviruses were found in 8.0% of subjects with acute respiratory tract infection, in comparison to 5.5% of nonrespiratory controls. Rhinoviruses were found most commonly in this group (24.7% vs. 16.6% of controls).¹⁷⁸ A survey of first respiratory tract illnesses in the first year of life using PCR with primers for 229E, OC43, and NL63 found coronaviruses in 13 of 82 (16%) infants.¹⁴⁸ As more studies are performed that span longer periods, sample properly matched asymptomatic controls, and include all four known respiratory HCoV strains, the true incidence is likely to become clearer.

The possible role of coronaviruses in the etiology of otitis media with effusion has been the subject of several studies that used PCR for 229E and OC43 in both nasal secretions and middle ear fluid. In one study, 92 children with acute otitis media were investigated. Coronavirus sequences were found in 16 children (17%), in the nasopharynx in 14 children, and in middle ear fluid in seven. This prevalence was less than that of both respiratory syncytial virus (26%) and rhinoviruses (32%).¹³⁸ Another 3-year survey of viral upper respiratory tract infections with or without otitis media in the United States used PCR for OC43, NL63, and 229E as well as for other respiratory viruses. Otitis complicated approximately 50% of upper respiratory tract infections in which respiratory syncytial virus, HCoVs, and adenoviruses were found and a smaller proportion in which other viruses (influenza, rhinovirus, metapneumovirus, and parainfluenza viruses) were detected.³⁶

Lower Respiratory Tract Disease

Pneumonia and Other Severe Lower Respiratory Tract Infections

The first evidence of a possible causative role of coronaviruses in lower respiratory tract disease was found in a serologic study of hospitalized infants during 1967 to 1970.¹⁰⁶ Infections with both HCoV-229E and

HCoV-OC43 were noted, and HCoV was the third most frequently occurring virus (behind respiratory syncytial virus and parainfluenza virus type 3), both in incidence and specifically associated with pneumonia and bronchiolitis. Many of these infants required oxygen. HCoV-229E was grown in tissue culture from oropharyngeal swabs obtained from two of the infants with pneumonia and rises in antibody.

With the increasing availability of PCR for detection of coronaviruses and the addition of two new HCoV strains, NL63 and HKU1, information about the presence of these viruses in children with serious respiratory tract disease has expanded greatly. A large number of studies have demonstrated that HCoVs can be found in the respiratory tract of 4% to 8% of children hospitalized with acute respiratory infection, often accompanied by coinfection with other respiratory tract viruses.^{32,35,61,86,96,127,146,156,167,180} A much smaller number of surveys have included age- and season-matched control children without respiratory symptoms. When these controls are properly chosen and studied, however, HCoV detection rates in well and ill children have been similar.^{39,142,159} It appears likely that coronaviruses are pathogenic in some instances whereas in others they are not, or persistent shedding of these viruses may occur, and it is difficult to assign an etiologic role in individual cases.¹⁰³

In newborns, apnea, bradycardia, and increased demand for oxygen have been described during coronavirus infection.^{39,59,160,161} One prospective nursery study, with sampling at regular intervals regardless of symptoms, associated HCoV-229E infection with symptomatic disease in high-risk neonates.⁵⁷ Another outbreak study in a neonatal intensive care setting implicated NL63 in acute symptomatic disease.⁴⁹

There is a suggestion that NL63 is seen particularly in croup.^{35,166,176} Carefully conducted epidemiologic studies do not link coronavirus infection or disease with Kawasaki syndrome.¹²

Infections in Children With Underlying Respiratory Disease or Immunodeficiency

Substantial evidence indicates that HCoVs can precipitate asthma attacks,^{73,77,108,114,133} although their role in this regard is clearly secondary to that of rhinoviruses and respiratory syncytial virus.⁷⁴ In a 2-year surveillance (1967–69) of 32 mostly atopic children aged 1 to 5 years hospitalized in Denver for severe, recurrent bouts of wheezing, 19 HCoV infections were diagnosed.¹⁰⁸ Six children were infected simultaneously with either parainfluenza virus or respiratory syncytial virus. Of the remaining 13 patients, all were symptomatic: three had mild wheezing, and seven had acute asthma attacks, two of which required intravenous therapy.

Several studies of HCoVs in children with cystic fibrosis have identified all four species by PCR.^{21,40} In a study from Brazil, HCoVs were found in 19 of 408 samples, with a correlation of NL63 infection with exacerbations of respiratory symptoms, although this did not hold up in a logistic regression model for independent association.⁴⁰ In a 2-year prospective Seattle study in 44 participants, HCoVs were detected in only three subjects, but in both upper airway and sputum samples.²¹

Coronavirus has been detected as the sole respiratory pathogen in upper and lower respiratory tract samples in immunocompromised children with pneumonia receiving chemotherapy or having received a solid-organ transplant as well as in adults undergoing HSCT.^{86,171} Respiratory disease in six immunocompromised children with coronavirus and no other viral, bacterial, or fungal pathogen detected by sensitive testing began as fever and rhinorrhea; only two children had cough at the time of first medical encounter.⁸⁶ Only one of three children had evidence of abnormalities on chest radiographs, although all six children required hospitalization for coronavirus-linked illness for 2 to 12 days. A prospective study with weekly sampling in 215 asymptomatic and symptomatic HSCT recipients of all ages during the first 100 days after transplantation demonstrated prolonged coronavirus shedding (frequently for 6 weeks, occasionally up to 12 weeks). Moreover, coronavirus was not found as a sole pathogen associated with pneumonia, demonstrating that coronavirus-associated pneumonia is relatively infrequent in immunocompromised patients and that the detection of coronavirus is probably insufficient evidence to assess causality.¹¹⁶

Severe Acute Respiratory Syndrome

SARS emerged in 2002 as a new infectious disease that originated in Guangdong Province, China, in November 2002. After a few sporadic

cases, the virus spread at first within China and then, through Hong Kong, to Vietnam, Singapore, Europe, Canada, and the United States. By the time the epidemic ended in the summer of 2003, there were 8096 probable cases in 29 countries and areas with 774 deaths (9.6% mortality).¹⁹² The total number of health care workers affected was 1706 (21.1% of all probable cases). Globally, children younger than 18 years likely accounted for only about 5% of cases. The severity of the syndrome appears to have been greater in adults and adolescents than in young children, and there was no reported mortality in children.¹⁹³ Further detail is provided in the sixth edition of this book.

Etiology

The etiologic agent of SARS is a novel coronavirus, the SARS-CoV, identified independently and collaboratively by multiple investigators.^{45,84,135,141} The virus was classified as a betacoronavirus, lineage B (HCoV-OC43 and HKU1 are in lineage A). The virus undoubtedly originated in animals, probably bats, and then spread to exotic animals kept for human consumption in southeastern China, and then to humans.^{31,65,78,89,94} The genome of the SARS-CoV is about 29,700 nucleotides in length and has a genetic organization similar to that of other coronaviruses. The SARS-CoV uses angiotensin-converting enzyme 2 as a key functional cellular receptor. The virus also binds to the C-type lectin CD209L (also known as L-SIGN) and DC-SIGN.^{72,88,93}

Epidemiology

Through case identification and rigorous implementation of barrier methods, the SARS epidemic was quenched after only about 8 months of activity despite the fact that the virus could potentially spread widely through aerosols. One well-described airplane cluster and several explosive community epidemics were well documented.^{129,197} Children with SARS are apparently less infectious than their adult counterparts.

Clinical Presentation

There are two large series of serologically proven pediatric cases of SARS.^{33,92} In Leung's series (median age, 12 years) the disease had many features similar to that in adults: onset with fever and systemic, influenza-like symptoms, followed by cough in 64% and diarrhea in 20%; progressive pneumonia, common in adults, appeared in only a small minority of children and mostly in adolescents.⁹²

Chest radiography and high-resolution computed tomography findings were similar to those found in adults, showing peripheral consolidations and ground-glass opacities, with pleural effusions being rare.¹¹ In spite of the apparent universality of viremia, no evidence of perinatal transmission to infants was documented.^{123,124,154,158,186,199} However, maternal SARS-CoV infection was associated with both maternal and fetal morbidity and mortality.^{123,124,158,185,186}

Specific Diagnosis, Treatment and Prevention

The World Health Organization and the Centers for Disease Control and Prevention developed case definitions for SARS.^{26,191} Laboratory diagnosis depended on antibody titer during illness or detection of virus in plasma or respiratory tract secretions using specific reverse transcriptase (RT)-PCR platforms.^{125,140} No specific treatment other than careful supportive care is recommended.

The mainstay of prevention of SARS was effective and enforced hospital infection control practices and quarantine procedures outside hospitals: isolation at triage in negative air-pressure rooms, use of appropriate masks and goggles or face shields while tending patients, and handwashing before and after contact with patients.³⁷

Middle East Respiratory Syndrome

The first report of Middle East respiratory syndrome (MERS) was in a man hospitalized in Jeddah, Saudi Arabia, in June 2012, who died of severe pneumonia and renal failure and from whose sputum a novel coronavirus was isolated.¹⁹⁸ This new betacoronavirus was initially called human coronavirus Erasmus Medical Center (HCoV-EMC).¹⁷³ In September 2012, a similar virus was identified from a patient with severe pneumonia who had been transferred from the Gulf region of the Middle East to London, United Kingdom, and was named human

coronavirus England 1.¹⁴ Later, this novel coronavirus was renamed MERS-CoV by global consensus.⁴¹ Multiple studies have reported outbreaks associated with health care facilities and with transmission in household contacts.^{9,46,128} As of March 2016, WHO had reported 1698 laboratory-confirmed cases of MERS-CoV infection in 26 countries with 609 deaths globally, an approximate 36% mortality rate (<http://www.who.int/emergencies/mers-cov/en/>). Most cases have been in adults living or traveling in the Arabian peninsula and with underlying chronic diseases or immunosuppression.

Etiology

MERS-CoV is a betacoronavirus, belongs to lineage C, and is closely related to *Tylonycteris* bat coronavirus HKU4 (Ty-BatCoV HKU4) and *Pipistrellus* bat coronavirus HKU5 (Pi-BatCoV HKU5).⁴¹ The widely expressed cell-surface protease dipeptidyl-peptidase 4 (DPP4, also known as CD26) was identified as a functional receptor for host cell entry.¹⁴⁵

Epidemiology

The epidemiology of MERS-CoV infection has not been well described. The role of bats has been investigated. In four countries in Europe and Ghana, Africa, viruses related to MERS-CoV were identified from 24.9% of *Nycteris* bats and 14.7% of *Pipistrellus* bats.⁵ In Saudi Arabia virus from one bat contained a 190-base-pair sequence in the large replicase gene identical to the analogous sequence from the human index case virus.¹¹³

The first definitive isolation of MERS-CoV in nonhuman animal species was reported from dromedary camels in an outbreak investigation in Qatar.⁶⁶ An analysis of a 4β2-kb partial viral sequence collected from one animal showed that the camel virus was almost identical to isolates collected from two human cases who had been working on the affected farm. In addition, neutralizing antibodies to MERS-CoV in persons with and without dromedary contact were detected only in those with contact.¹⁵⁰

A study from United Arab Emirates showed that dromedaries had antibodies against MERS-CoV in sera obtained in both 2003 and 2013,¹¹⁵ and positive antibody responses were also detected among dromedary in several countries in Africa, such as Nigeria, Tunisia, and Ethiopia.¹⁵¹ MERS-CoV thus circulated among camels long before human cases were identified, and MERS may also have been underdiagnosed in humans outside the Arabian Peninsula. In a serosurveillance of domestic animals, no evidence of infections in cows, goats, or sheep has been found.¹⁵¹

All known MERS-CoV infections can be traced to countries in the Middle East, primarily Saudi Arabia. In early reports, limited person-to-person spread in families and health care settings was demonstrated. Calculations from these early data suggested a reproductive coefficient less than 1, indicating a likely low pandemic potential.¹⁸ However, in the large, predominantly nosocomial 2015 outbreak in the Republic of Korea, a potential episode of "superspreading" was described in which a single patient infected more than 80 other individuals in an emergency department setting.⁸²

Clinical Presentation

The incubation period for MERS has been reported to be from 2 to over 14 days with a mean of 5 days from exposure to symptom development.⁹ Patients with MERS often develop symptoms with fever, chills, cough, sore throat, myalgia, and arthralgia followed by dyspnea and rapid progression to pneumonia requiring ventilatory and other organ support within the first week.^{3,8,9} Of note, some patients with fever, myalgia, and arthralgia have severe disease prior to or without the development of pneumonia. Other common symptoms have included nausea, vomiting, diarrhea, sore throat, myalgia, and headache. Some of those infected, including children and adolescents, have been asymptomatic or only mildly affected.

Many clinical features are similar among patients with MERS and SARS. However, it appears that patients with MERS have higher respiratory tract viral loads during the first week of the illness, a shorter time from illness onset to clinical presentation and requirement for ventilatory support, and a higher overall case-fatality rate than do patients with SARS.²⁰¹

There has been only one summary of proven MERS-CoV infections in children.¹¹² Of 11 pediatric cases reported, nine were asymptomatic. A 14-year-old morbidly obese girl with Down syndrome was hospitalized with pneumonia but recovered uneventfully. A 2-year-old with cystic fibrosis died after a prolonged hospital course with respiratory and multiorgan failure. In one further report from the World Health Organization, a 14-month-old child in Italy exposed to an adult relative who had returned from Amman, Jordan, with proven MERS developed a mild respiratory illness with PCR-proven MERS-CoV infection and made a full recovery.¹⁹⁴

Diagnosis

The World Health Organization and the US Centers for Disease Control and Prevention have published case definitions and urge the early submission of respiratory samples, preferably from the lower respiratory tract, for PCR diagnosis, using laboratories with approved protocols and reagents. Serologic diagnosis has not been standardized^{27,193} but has been important in outbreak investigations.

Treatment

Multiple experimental treatment modalities have been attempted, including ribavirin, interferon, lopinavir/ritonavir, and convalescent plasma, but data are lacking on the benefits of these therapies.^{4,100,143,157,164}

Prevention

In the absence of specific information about the mode of MERS-CoV spread and because of the high lethality of infection, full barrier precautions are recommended for all contacts, with details very similar to the precautions that were used in the SARS epidemic.²⁸ Strict adherence to good infection control practices is essential because of the potential for nosocomial spread (Fig. 188.3).³⁴

Enteric Human Coronavirus

Coronaviruses are important causes of diarrhea in young calves and pigs, and therefore attempts have been made to find human coronaviruses in the stool and to associate them with enteric disease. Most early studies used electron microscopy to detect coronavirus-like particles (CVLPs), but because such particles have, in many studies, appeared as frequently in well subjects as in those with diarrhea, their relevance or authenticity has been questioned.^{44,98,119,134} Isolated reports of coronavirus growth in vitro from cases of diarrhea^{97,199} have similarly not been confirmed.

The firmest link of CVLPs to human enteric disease may be with gastroenteritis in the very young, especially neonatal necrotizing enterocolitis (NEC). An epidemiologic investigation of NEC was conducted in two hospitals in France, one with and one without an NEC outbreak.²⁹ Within each hospital, newborns with “no pathologic

Floor plan

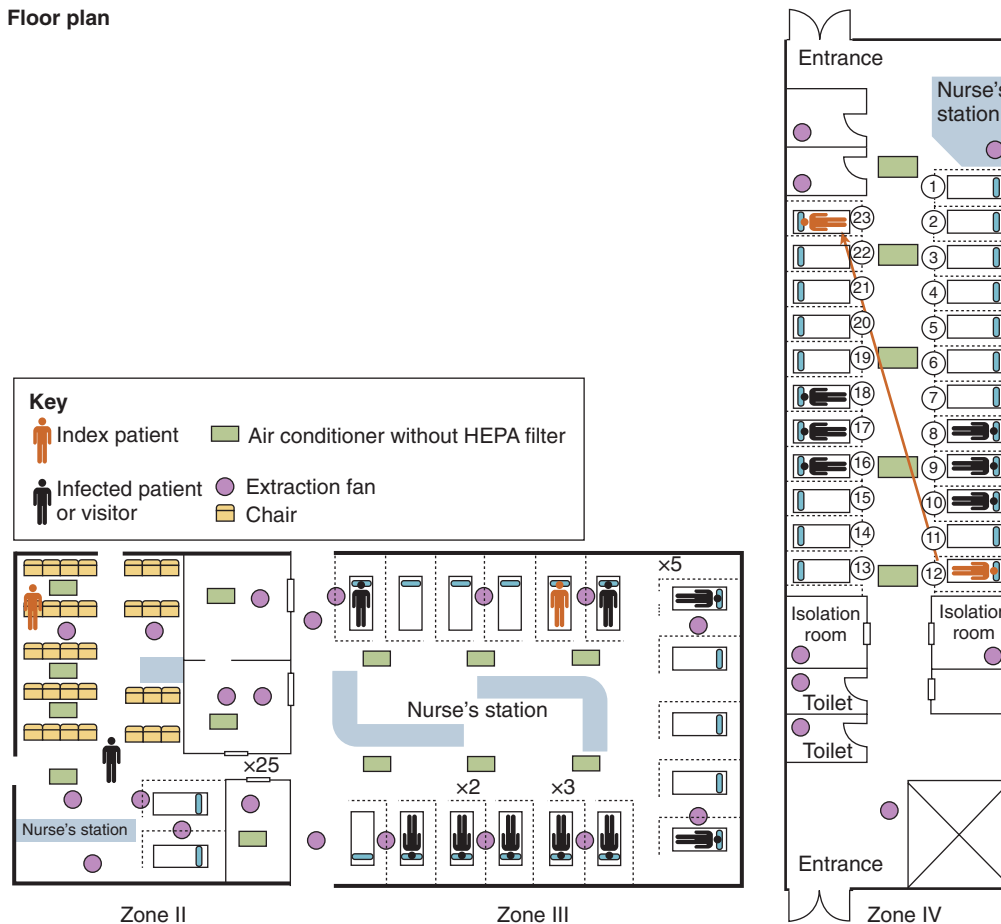

FIG. 188.3 Transmission of Middle East respiratory syndrome coronavirus (MERS-CoV) within a hospital setting. The index patient is shown in red and infected patients and visitors in black in various zones in an emergency room (ER). Over 3 days, the index patient moved from the sitting area (left) to a bed in the central zone of ER (middle), to a preadmission zone of ER (right), and from bed 12 to bed 23 in that zone. MERS-CoV transmission occurred despite the fact that the distance from the index patient's bed to beds of other patients was as great as 6 meters; “x2” indicates two infected MERS cases, successively, in patients or visitors occupying or visiting that bed or that zone. Average ventilation rate in the ER was maintained at three air changes per hour, and all zones in the ER were covered by the same air handling unit. (From Cho SY, Kang J, Ha YE, et al. MERS-CoV outbreak following a single patient exposure in an emergency room in South Korea: an epidemiological outbreak study. *Lancet*. 2016;388(10048):994-1001.)

occurrence” were used as controls. In the NEC-free hospital, no CVLPs were found in the stools of 21 controls, but two patients with mild diarrhea had CVLPs. In the NEC hospital, 23 of the 32 (72%) NEC patients had fecal CVLPs compared to 3 of 26 (11.5%) controls ($P < .02$). Similar nursery outbreaks of severe diarrhea or NEC in Italy and the United States have been studied by electron microscopy, with similar significant association of CVLPs with disease.^{179,62,149}

More recently, clinical studies have used RT-PCR directed at the four community-acquired respiratory coronavirus species in simultaneously collected stool samples and nasopharyngeal swabs from children in the community and the hospital who have acute gastroenteritis (AGE).^{48,76,130,131,153} These studies have been conducted in the United States, Finland, and Slovenia and have failed to identify HCoV as an important cause of AGE. One large study, which included asymptomatic control samples, evaluated 878 samples from children with gastrointestinal complaints during 2 years, and detected one of the four HCoV species in 22 children.¹⁵³ However, in all but four cases, either rotavirus or norovirus was also found. About half the children had respiratory as well as gastrointestinal symptoms. A prospective study in Finland studied HCoV in hospitalized children with AGE ($n = 172$), acute respiratory tract infection ($n = 545$), or both ($n = 238$) using RT-PCR.¹³¹ As in Risku’s previous study, HCoVs were detected in the stools of children with AGE, but usually in the presence of other well-known gastroenteritis viruses, and concomitantly in the respiratory tract. To date, most symptomatic children with HCoV RNA in the stool also have evidence of coinfection by viruses with known gastrointestinal pathogenicity. Thus, the currently described species of community-acquired respiratory HCoV do not appear to play a significant causal role in childhood gastrointestinal illness.^{76,131,153} It is possible that some other, as yet undescribed, HCoV species play a role in diarrhea. Controlled longitudinal studies of diarrheal outbreaks in nurseries using PCR have not been published to date.

Neurologic Diseases

Coronaviruses are the cause of some animal neurologic disorders, including a murine demyelinating disease with some features resembling multiple sclerosis. In humans, a serosurvey of HCoV infection in southern Finland discovered evidence of HCoV-OC43 infection in six patients with acute neurologic episodes, including one with polyradiculitis.¹⁵² A case of acute demyelinating encephalitis accompanying OC43 respiratory tract infection was described in which OC43 RNA was detected by PCR in the spinal fluid.¹⁹⁶ Several observations have suggested a possible role of coronavirus infection in multiple sclerosis including: (1) isolation of coronaviruses (SK + SD) from the central nervous system tissue of two patients with multiple sclerosis,²⁰ (2) demonstration that coronavirus SD can cause demyelination in a primate model,¹²¹ (3) direct visualization of CVLPs in the brain of a patient with multiple sclerosis,¹⁶⁸ and (4) identification by *in situ* hybridization or PCR of coronavirus RNA in the brains of patients with multiple sclerosis.^{6,120,165} However, coronaviruses SK and SD are antigenically and genetically very similar to mouse hepatitis virus and were isolated with the use of mouse tissues; the possibility that these isolates were of mouse origin has not been excluded. Other studies have failed to demonstrate coronavirus RNA in the central nervous system tissue of patients with multiple sclerosis¹⁶³ or have found such RNA in the same proportion of patients with demyelinating diseases as in controls.⁴² Further investigation will be needed to establish whether HCoVs are related causally to any neurologic disease in humans.

LABORATORY DIAGNOSIS

Virus Isolation

Community-Acquired Respiratory Coronaviruses

Human embryo tracheal or nasal mucosal organ cultures were first used for primary isolation of multiple community-acquired respiratory HCoV strains, including B814, OC43, and several less well characterized strains.^{107,170} OC43 was subsequently adapted to growth in monkey kidney, BSC-1, and rhabdomyoma cells.^{19,155} The 229E-type strains were shown to replicate and produce a cytopathic effect in secondary human embryo kidney⁶⁸ or certain diploid cell lines: WI-38, MRC-5, and

MA-177.^{67,79} There has been a report of the growth and cytopathic effect of OC43-like and HKU1 strains in the HuH7 hepatocarcinoma cell line.^{56,172} NL63 strains grow directly from clinical samples in tertiary monkey kidney cells, with subsequent growth in LLC or Vero cells.^{55,175}

Virus Detection Techniques

Community-Acquired Respiratory Coronaviruses

Respiratory coronaviruses can be found in clinical samples by direct antigen detection techniques or by nucleic acid detection. Immunofluorescence^{75,111,161} and antigen-detecting ELISA have been used successfully for the diagnosis of HCoV infection,^{73,99,114} but nucleic acid detection using PCR techniques has opened up the field of coronavirus diagnosis. Not only is this method the most sensitive for all the known strains of HCoV, but it can also be designed to detect new strains.⁴⁹ Attempts to design a set of “pan-coronavirus” primers have, however, always led to suboptimal sensitivity.^{49,61} The exact design of the tests greatly influences their sensitivity and specificity.

Serodiagnosis

A rise in antibody titer after day 28 of onset of symptoms is the gold standard for diagnosis of SARS-CoV and MERS-CoV infection, most commonly by ELISA or immunofluorescence assay in Vero-E6 cells. The finding of antibody in convalescent serum is highly specific, although there are one-way cross-reactivities with both 229E and, notably, OC43 for SARS-CoV.³⁰ For respiratory coronaviruses, complement fixation,^{25,106,110,118,152} hemagglutination inhibition (for HCoV-OC43 only),⁸¹ neutralization,⁴⁷ ELISA,^{24,43,63,83,99} indirect hemagglutination,⁸⁰ and Western blot have been used.¹³⁹

PREVENTION AND TREATMENT

Barrier methods with attention to infection control practices were extraordinarily successful in the limitation and final elimination of the SARS epidemic and in limiting the MERS epidemic. The high reinfection rate with the respiratory HCoVs as well as the number of related strains suggests that a vaccine may be ineffective in preventing HCoV-caused respiratory illness. There are no known effective antivirals for the community-acquired respiratory coronaviruses.

Hantaviruses

Louisa E. Chapman[†] • C.J. Peters • James N. Mills • Kelly T. McKee Jr

HISTORICAL PERSPECTIVE

Hantaviruses are the etiologic agents of a diverse group of rodent-borne hemorrhagic fevers that are responsible for considerable morbidity and mortality worldwide. Although recognized by Western Hemisphere medical practitioners relatively recently, clinical syndromes now known to be associated with these viruses have been described by traditional practitioners across the globe from antiquity.^{31,127} Russian scientists documented sporadic outbreaks of febrile renal failure with hemorrhage in the eastern Soviet Union between 1913 and 1930,²¹ and Japanese and Soviet scientists recognized annual outbreaks of a similar syndrome in Manchuria and Siberia between 1932 and 1935.^{52,62,63,100,133,153,154,204}

In 1934, Swedish scientists described a novel disorder, characterized by fever, abdominal and back pain, and renal abnormalities.^{75,161,210,246} Epidemic disease with these features occurred among German and Finnish troops stationed in Lapland during World War II.^{94,210} Physicians called this syndrome nephropathia epidemica (NE). North American medical practitioners initially became acquainted with a similar syndrome in the early 1950s when a previously unrecognized febrile illness characterized by shock, hemorrhage, and renal failure developed in thousands of soldiers serving with United Nations forces during the Korean War. Physicians called this syndrome, which had a case-fatality rate of 5% to 15%, epidemic hemorrhagic fever.^{52,154}

In 1953, Gajdusek⁶² noted similarities among epidemic hemorrhagic fever, the severe and frequently fatal Far Eastern diseases described by Soviet and Japanese scientists, and the Scandinavian disorder and proposed a common origin. Subsequent validation of this hypothesis (see **Organism**) ultimately prompted adoption of the collective term hemorrhagic fever with renal syndrome (HFRS) to describe this clinical entity characterized by varying degrees of renal dysfunction and hemorrhage with fever.

In June 1993, investigation of a cluster of unexplained respiratory deaths in previously healthy young adult residents of rural areas in the southwestern United States led to recognition of a “new” febrile disorder in North America. Application of sophisticated serologic and virologic tools to diagnostic specimens from patients with this disease quickly pointed to a hantavirus related to, but distinct from, those causing HFRS.^{120,164} This disorder, now called hantavirus pulmonary syndrome (HPS) or hantavirus cardiopulmonary syndrome (HCPS), appeared to be different clinically from classic HFRS; however, as virologic and epidemiologic studies of the etiologic agent and its reservoirs were completed, similarities to other hantaviruses became apparent. Subsequent studies searching for hantaviruses associated with febrile pulmonary rather than renal disease established HPS as endemic throughout the Western hemisphere and identified a large number of unique hantaviruses associated with rodents indigenous to the Americas, not all of which have been associated with human disease^{31,50,147} (Fig. 189.1).

Twenty-four hantavirus species were recognized by the International Committee on Taxonomy of Viruses (ICTV) in its 2015 release.¹ Molecular analyses of these and more recent isolates or sequences have revealed three to four or more phylogenetic clusters, thus reflecting the complex evolutionary history and diverse range of mammalian hosts harboring these agents.^{11,78,222}

ORGANISM

Classification and Antigenic Composition

The genus *Hantavirus* of the family *Bunyaviridae* was defined in 1985.^{191–194} Members of the genus *Hantavirus* are classified among the bunyaviruses because of their shared morphologic, physicochemical, and molecular properties. Like other members of the *Bunyaviridae* family, hantaviruses are negative-stranded, lipid-enveloped RNA viruses with tripartite genomes; genomic segments are designated as large (L, approximately 6500 nucleotides, encodes the virus L protein, an RNA-dependent RNA polymerase), medium (M, approximately 3600 nucleotides long, encodes the envelope glycoprotein precursor [GPC], which is processed into two transmembrane glycoproteins: mature Gn and Gc glycoproteins), and small (S, 1600–2004 nucleotides long, encodes an RNA-binding nucleocapsid protein, the N protein).^{90,147,195} Puumala virus and some other hantaviruses also encode a nonstructural protein NS that can function as a weak interferon inhibitor.¹⁶¹

Also like other bunyaviruses, hantaviruses display Golgi-associated morphogenesis and usually acquire their envelopes by budding into intracytoplasmic vacuoles.¹⁹⁴ However, they are serologically distinct from other family members and possess unique terminal genomic sequences.^{192,195} The genus *Hantavirus* contains the only members of *Bunyaviridae* that lack arthropod vectors. As a general rule, each of the hantaviruses associated with human disease is adapted to a specific rodent host species and depends on persistent infection in wild rodents for maintenance in nature.

Physical Properties

Morphologically, hantaviruses are spherical or pleomorphic, 70 to 210 nm in diameter, and have a surface glycoprotein complex consisting of Gn interconnected with Gc embedded in a lipid bilayer envelope.²²² These Gn and Gc tetramers form spikes that protrude approximately 10 nm from the membrane, creating a fourfold symmetry that is apparently unique among enveloped viruses (Fig. 189.2).²²²

Integrins have been implicated as primary host cell surface receptors for hantaviruses, with $\alpha 5\beta 3$ integrin serving as a receptor of pathogenic hantaviruses and $\alpha 5\beta 1$ integrin as a receptor for nonpathogenic hantaviruses in vitro.^{42,68,222} The viral surface glycoproteins (Gn and Gc) mediate virus attachment to cells. The virus appears to use a variety of pathways for entry (e.g., both clathrin-dependent and clathrin-independent endocytosis).²²² After internalization, virions migrate to

[†]Deceased.

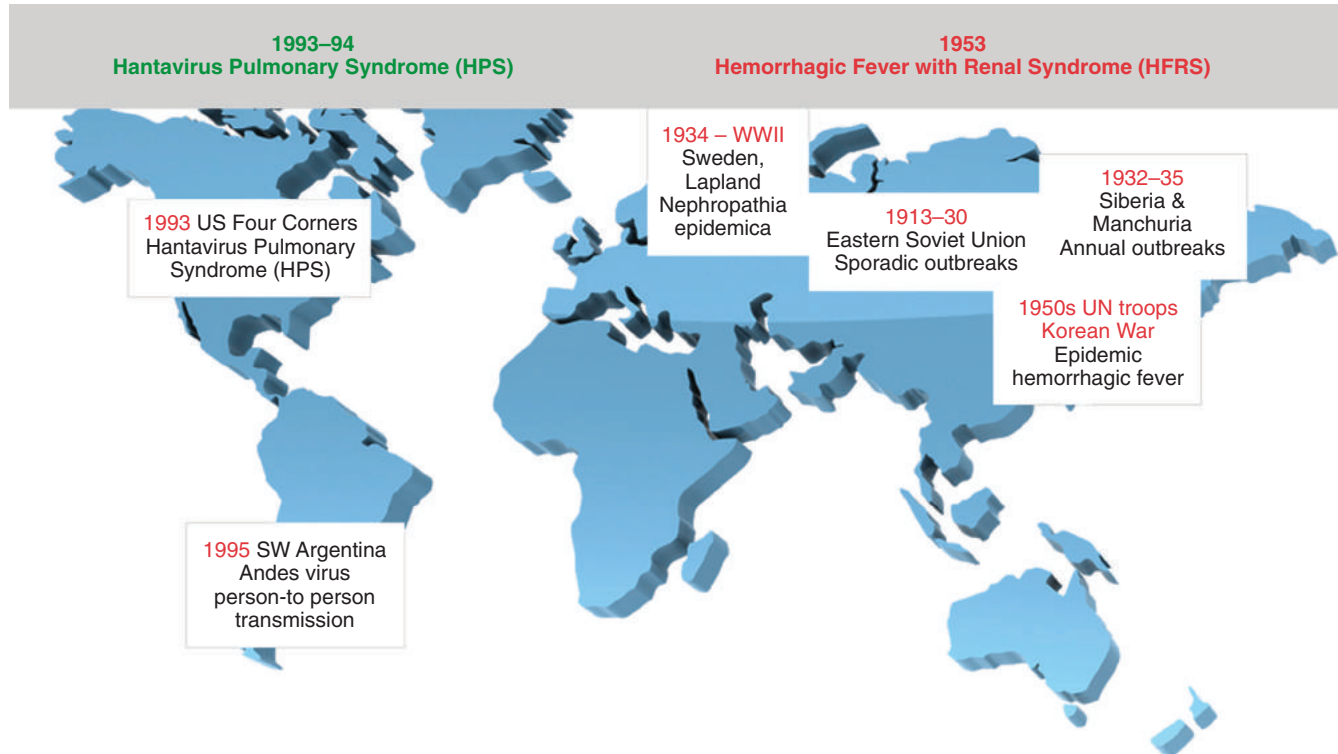

FIG. 189.1 Map demonstrating the temporal and geographic recognition of human diseases associated with hantavirus infections. UN, United Nations; WWII, World War II.

endosomes, where low pH triggers conformational changes resulting in fusion of the virus and endosomal membranes and release of virion ribonucleocapsid (RNP) cores into the cell cytoplasm. The virion-associated RNA-dependent RNA polymerase transcribes its negative-sense RNA segments to produce messenger RNAs (mRNAs) encoding the viral proteins (N protein, L polymerase protein, and the GPC).^{90,222} Details of transcription are still unclear, but the polymerase appears to be involved in so-called 5'-cap snatching (similar to that for other negative-sense RNA viruses), as well as transcriptase, replicase, and endonuclease functions critical for mRNA transcription, as well as for subsequent translation and replication activities.^{147,222} The GPC mRNA is translated by membrane-bound ribosomes and by analogy with other *Bunyaviridae*, presumably in the Golgi complex and endoplasmic reticulum. The N and L mRNAs are translated by free ribosomes.¹⁴⁷ The multifunctional N protein protects the virus genomic RNA (vRNA) from nuclease degradation by limiting access of RNA to host nucleases and is involved in encapsidation of vRNA and antigenomic RNA (cRNA), but not viral mRNA. The N protein plays an active role in virus RNA transcription, interacts with ribosomal protein RPS19 to facilitate the loading of the 40S ribosomal subunit onto the virus mRNA, and plays an active role in virus assembly.¹⁴⁷ N protein activities are linked not only to fundamental requirements of viral replication but also to interference with intracellular processes of the host cell, including inflammatory processes.^{90,113}

Hantavirus assembly involves the RNP core (containing the vRNA and N and L proteins) and the acquired host cell membrane containing the embedded virus Gn and Gc glycoproteins. Direct interaction of the virus Gn or its cytoplasmic tail with N protein and RNA is believed to facilitate virus assembly.¹⁴⁷ Virus glycoproteins are believed to determine the site of virus assembly and budding. The Gn and Gc proteins of so-called New World (endemic to the Western Hemisphere) hantaviruses accumulate in the Golgi, but the process by which virions make their way to the cell surface remains poorly defined.^{147,222} Two sites of New World hantaviral maturation have been described. During infection in polarized epithelial cells, Black Creek Canal virus was released from the apical membrane,¹⁸⁵ but Andes virus was released from both apical and basolateral sites in primary hamster epithelium.¹⁸⁶

Susceptibility

Hantavirus transmission may occur through indirect contact with contaminated environmental surfaces. Puumala virus excreted by experimentally infected bank voles into bedding maintained infectivity to recipient voles at room temperature for 12 to 15 days.¹⁰² Knowledge about the survival time in the environment in the absence of disinfection is limited, but survival appears to be temperature dependent. Infectivity persists in dried cell culture medium for as long as 2 days and in neutral solutions for several hours at 37°C or several days at lower temperatures.²³ Infectious Hantaan virus was detected after 96 days under “wet” conditions at 4°C, and it remained viable for 2 minutes in 30% ethanol.⁸¹ Cell culture supernatants of Puumala and Tula hantaviruses remained infectious for 5 to 11 days at room temperature and for as long as 18 days at 4°C but were inactivated after 24 hours at 37°C.¹⁹¹

However, hantaviruses are inactivated readily by lipid solvents and most disinfectants, including dilute hypochlorite solutions, detergents, ethyl alcohol (70%), most general-purpose household disinfectants, and β -propiolactone (0.1% at 4°C for 3 days).^{75,116,181} Limited studies with Hantaan virus have shown sensitivity to a pH of 5 or less and to temperatures of 56°C or higher.⁷⁵

Laboratory Propagation and Tissue Culture Growth

Hantaviruses are fastidious but can be grown in culture through serial blind passage. They routinely establish persistent, noncytolytic infections and generally do not replicate to high titer.^{75,192,194} The prototype hantavirus, Hantaan virus, was isolated in 1978,¹³⁵ and it was propagated in cell culture in the A-549 cell line in 1981.⁶⁰ Vero E-6 cells subsequently were found to be a better cell culture system for this and other hantaviruses.⁷⁵ Hantaviruses have been isolated and propagated through direct inoculation of homogenates of infected tissue from wild-caught rodent hosts onto cell lines or after amplification through serially infected, colonized rodent hosts.^{53,60,73,75,135,166,196,239} Recovery of hantaviruses from human specimens has been difficult and infrequent. Some hantaviruses have been isolated in cell culture, but many are known only from genetic material amplified from human or rodent tissue. Laboratory infection of persons working with cell culture-adapted Hantaan virus has occurred occasionally, but laboratory transmission of hantaviruses from infected

FIG. 189.2 Transmission electron micrographs reveal the ultrastructural appearance of several virus particles, or virions, of a hantavirus known as Sin Nombre virus. This is the hantavirus most commonly responsible for hantavirus pulmonary syndrome in the United States. In November 1993 the specific hantavirus that caused the Four Corners outbreak was isolated. (A) Using tissue from a deer mouse that had been trapped near the New Mexico home of a person who had contracted the disease, the Special Pathogens Branch at Centers for Disease Control and Prevention grew the virus in the laboratory. (B) Shortly afterward, and independently, the US Army Medical Research Institute of Infectious Diseases also grew the virus from a person in New Mexico who had contracted the disease, as well as from a mouse trapped in California. (Courtesy Centers for Disease Control and Prevention [CDC]/Cynthia Goldsmith, Luanne H. Elliott, Brian W. Mahy, and the CDC Viral Special Pathogens Branch.)

rodents to humans is a particularly common occurrence.^{44,49,104,130,132,142,221} Consequently, attempts to propagate the virus in cell culture or rodents should be performed only when using biosafety level 3 or 4 facilities and practices.^{23,27}

Transmission

Hantaviruses are zoonotic; with few exceptions, each of the hantaviruses that are pathogenic for humans is naturally associated with a distinct rodent species or subspecies in which it establishes chronic infection (Table 189.1). Hantavirus infection of rodents produces brief viremia that results in dissemination of virus to the lungs, salivary glands, and kidneys. The infected rodent sheds virus in urine, saliva, and (to a lesser extent) feces persistently or occasionally throughout its life, despite the development of neutralizing antibodies.¹³⁴ In contrast to early laboratory data suggesting that infection does not adversely affect host longevity or reproduction, field evidence is accumulating that deer mice infected with Sin Nombre virus have reduced survivorship in nature.^{3,47,48,144} Vertical transmission has not been demonstrated, and pups born to infected dams appear to be protected by maternal antibody.^{46,103,159} Enzootic infection appears to be maintained by exposure to nesting materials contaminated with infectious secretions, by grooming, and by intraspecies biting.^{48,130,134}

Humans typically become infected with hantaviruses after contact with saliva or excreta from infected rodents (or material contaminated by these), by inhalation of small-particle aerosols, by direct contact of infectious materials with broken skin or mucous membranes, or by percutaneous inoculation of infectious materials (e.g., rodent bite). The primacy of respiratory droplets or airborne particles as the mode of transmission to humans is supported by evidence from outbreaks of disease among laboratory workers and sporadic cases resulting from brief exposure to rodent-infested habitats.

The risk of human hantavirus infection is a function of the density of the local rodent reservoir population, the prevalence of infection among rodents, and the frequency of activities that result in contact between humans and rodents or rodent excreta. Individual hantavirus infections usually occur when humans disturb rodent habitats or rodents enter human housing.²⁴⁵ The risk for contracting disease after rodent exposure remains unquantified; however, one serosurvey suggested that persons in North America whose occupation entails close physical contact with rodents have a low risk for acquiring hantavirus infection.⁶¹ Epidemics generally are associated with changes in the behavior of human populations that result in large-scale exposure of persons to rodent-infested areas (e.g., military maneuvers, agricultural or forestry activities) or environmental changes that result in rapid increases in

the abundance of certain rodent host species (e.g., increased availability of food or preferred habitat).^{158,241}

Person-to-person transmission of hantaviruses associated with HFRS has not been demonstrated. The experience with HPS has been similar in North and Central America.²³³ However, interpersonal spread clearly occurred during a 1996 HPS outbreak in southern Argentina.^{56,235} Subsequent independent investigations support this observation by having identified clusters in Argentina and Chile that suggest person-to-person transmission associated with Andes virus.^{125,151,231} Interpersonal transmission thus appears to be an infrequent but clear feature peculiar to Andes virus^{29,150} (see Fig. 189.1).

EPIDEMIOLOGY

Geographic Distribution

Approximately 28 hantavirus genotypes are currently recognized as causing human disease, although many of them have not been fully characterized, and the reservoirs of a few have not been clearly determined. Only 15 of the known pathogenic genotypes are currently recognized as distinct species by the ICTV (see Table 189.1). Nevertheless, several other hantavirus genotypes are associated with distinct host species, occur in disjunct geographic areas, and are individually studied and commonly referred to in the literature. Therefore, we believe that listing those names is important (Table 189.1). In addition, there are at least 58 named hantavirus genotypes with no known association with human disease. This list will continue to grow and be modified as surveillance increases our knowledge of genetic relatedness among viruses and hosts improves.

Hantaviruses have been found on every continent except Antarctica. All rodent-borne hantaviruses are associated with four subfamilies of rodents in the large superfamily Muroidea. These are the Old World rats and mice (subfamily Murinae), the New World rats and mice (subfamilies Sigmodontinae and Neotominae), and the voles and lemmings (subfamily Arvicolinae). With the exception of HFRS caused by Seoul virus, hantavirus diseases occur almost exclusively in rural areas. Hantaan virus, the cause of classic HFRS, is carried by the striped field mouse, *Apodemus agrarius manchuricus*, which is distributed across eastern Russia, China, and the Korean peninsula.¹³⁵ The principal reservoir for Puumala virus, the etiologic agent of the milder HFRS variant (NE) found in Scandinavia, northern Europe, and Russia west of the Ural Mountains, is the bank vole, *Myodes glareolus*.¹⁹⁸ Puumala is the sole cause of HFRS in Nordic countries.¹⁶² Finland has the highest recognized annual incidence of NE (case-fatality rate, <0.4%).¹⁶²

TABLE 189.1 Named Genotypes of Hantaviruses Known to Be Pathogenic for Humans

Virus	Principal Reservoir	Known Distribution of Virus	Disease Association ^a
Old World Rodent-Borne

^aAn additional 58 hantavirus genotypes not known to be associated with human disease are not listed here.

^bVirus species recognized by the International Committee on the Taxonomy of Viruses.

^cThe taxonomy of the genus *Oligoryzomys* in general and *O. flavescens* in particular is still unresolved. The uniqueness of the viruses these rodents carry is also debated. HFRS, Hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome.

In Europe, at least four viruses have been linked etiologically with HFRS: Puumala, Tula, Saaremaa, and Dobrava; Tula virus is associated with voles (*Microtus* spp.); Saaremaa virus is hosted by a subspecies of the striped field mouse (*Apodemus agrarius agrarius*); Dobrava virus is associated with *Apodemus flavicollis*, the yellow-necked field mouse.^{4,7,9,10,73,178,179} *Rattus* spp. (primarily the brown rat, *Rattus norvegicus*) serve as reservoirs for the Seoul-like viruses identified worldwide; human infections have been seen most frequently in eastern Asia. Outbreaks of severe, and occasionally fatal, HFRS among animal handlers and laboratory scientists have been caused by exposure to laboratory rats with inapparent infection with Seoul-like viruses.¹³² Although infections with Dobrava and Saaremaa viruses are more likely to be fatal, Puumala virus remains the most common cause of HFRS in Europe.¹⁶²

Genome sequences of a novel hantavirus species have been detected in an African wood mouse (*Hylomyscus alleni*) in Guinea.¹¹² This agent, Sangassou virus, was more similar to Eurasian hantaviruses than to those causing HPS in the Western Hemisphere. Neutralizing antibodies to Sangassou virus were subsequently (and retrospectively) detected in sera from two human patients with fever of unknown origin in Sangassou Village.¹¹⁴ The virus is sufficiently distinct to represent a separate clade.

Numerous hantaviruses associated with native muroid rodents are known in the Americas (see Table 189.1). Several, all associated with New World rats and mice, are of medical importance in the United States.¹⁷⁵ The deer mouse, *Peromyscus maniculatus*, is the reservoir for Sin Nombre virus, the agent associated most frequently with HPS in the United States and Canada (Fig. 189.3).^{34,54,146} This rodent is distributed widely over the United States, Canada, and parts of Mexico. In addition, HPS cases in

the eastern United States have been associated with New York virus (hosted by the white-footed mouse, *Peromyscus leucopus*) and Monongahela viruses (also hosted by the deer mouse), which are closely related to Sin Nombre virus.^{88,207} Rare cases of HPS also have been associated with Black Creek Canal virus, which is associated with the hispid cotton rat (*Sigmodon hispidus*) and Bayou virus, hosted by the marsh rice rat (*Oryzomys palustris*).^{86,106,109,163,185,217} Several hantaviruses associated with voles (Arvicolinae) in North America are not associated with human disease: Prospect Hill virus has been recovered from meadow voles (*Microtus pennsylvanicus*) in Maryland,²³⁸ and related but distinct hantaviruses (Bloodland Lake and Isla Vista) have been shown in other voles by detection of genetic sequences by reverse transcriptase-polymerase chain reaction (RT-PCR).^{87,208} The Old World, murine-borne Seoul virus, introduced by the brown rat, has been associated with human infections in several large cities throughout the Americas, but acute (HFRS-like) disease has been recognized and confirmed only in Recife, Brazil.^{37,71,72,126}

South America clearly has surpassed North America in numbers of human HPS cases and numbers of hantaviruses and host species identified.^{13,91,232,234} All HPS-causing hantaviruses in South America are associated with sigmodontine rodents. Some of the most important viruses include the following: Andes virus in southern Argentina and Chile; Lechiguanas virus in central Argentina; Laguna Negra virus in northern Argentina, Paraguay, and Bolivia; Juquitiba virus in Brazil and eastern Paraguay; and Choclo virus in Panama. Numerous other hantaviruses, both pathogenic and not known to be pathogenic, occur throughout South America (see Table 189.1). Although HPS is clearly a panhemispheric disease, all HPS agents identified or suspected to date

FIG. 189.3 The deer mouse, *Peromyscus maniculatus*, the carrier of Sin Nombre virus, the most common agent of hantavirus pulmonary syndrome in North America. (Courtesy Centers for Disease Control and Prevention Special Pathogens Branch.)

belong to a single genetic group of hantaviruses and are associated with two subfamilies of rodents, the Neotominae (North America) and the Sigmodontinae (primarily Central and South America). These rodent species are restricted to the Americas, in accordance with findings that HPS is an exclusively Western Hemisphere disease.¹⁵⁷

One finding has been the apparently widespread occurrence of a divergent clade of hantaviruses associated with a group of small mammals unrelated to rodents, the insectivores (shrews and moles, order Soricomorpha).²⁴⁰ Although Thottapalayam virus and its association with the common house shrew (*Suncus murinus*) have been recognized since 1971,²⁰ this association was thought to be a unique exception. At least 27 newer insectivore-borne hantaviruses have been described from North America, Asia, Europe, and Africa.²⁴⁰

Finally, and most recently, approximately five hantaviruses have been reported in association with bats (order Chiroptera).²⁴⁰ Clearly, the association of hantaviruses with insectivores and bats is ancient, and understanding their distribution and evolution will be a challenge. Nevertheless, none of these bat, shrew, or mole viruses has so far been associated with human disease.

Seasonal Patterns

The natural population cycles of rodents and the seasonal nature of certain human behaviors result in a pattern of human hantavirus disease that varies seasonally and annually.^{21,31,63,127,219} Although incidence varies by season, cases of hantavirus-associated human disease are recognized year round in all disease-endemic areas.^{24,107,128,198} In eastern Asia and Russia east of the Ural Mountains, HFRS occurs primarily during late fall and early winter, with smaller peaks in spring and summer. Most Scandinavian HFRS occurs between late summer and early spring, whereas European HFRS in warmer regions (e.g., France, Belgium) tends to peak in spring. In the Balkans, the presence of multiple hantavirus-host combinations results in a more diffuse seasonal distribution of human disease.

Persons whose occupations or avocations bring them to rural settings, such as agricultural workers, foresters, biologists, hunters, campers, and soldiers stationed in the field, are at greatest risk for contracting HFRS. HFRS caused by Seoul virus tends to occur throughout the year, but there are conflicting descriptions of a seasonal occurrence of Seoul virus infection as well.^{33,129} Presumably because of the peridomestic nature of the reservoir, cases of Seoul virus disease are also less likely to have a skewed age and sex distribution than are rural hantavirus infections.

The temporal distribution of HPS cases in the United States displays strong seasonality. Maximum numbers of cases occur in May, June, and July, whereas minimum case numbers are seen during December, January, and February.¹⁴⁶ However, environmental and geographic factors influence this pattern¹⁵⁷; HPS cases have been identified throughout the winter and early spring.^{24,25,34,70,241} Seasonal patterns vary by region in the United States; in the midwestern and northwestern regions the highest proportion of cases occur in May, whereas cases peak in July in the southwestern region.¹⁴⁶

Prevalence and Incidence

Worldwide, human hantavirus infections may number in the hundreds of thousands of cases annually.²⁴¹ Because of the predominantly rural nature of the disease and its prevalence in developing regions of the Eurasian land mass (e.g., rural China), accurate case reporting (and statistical data) for HFRS is challenging. Researchers have estimated that 100,000 or more cases of HFRS may occur each year in China.²⁰⁵ One report suggested an incidence of 1.6 to 29.6 per 100,000 population during 1980.¹⁰⁰ In the former Soviet Union, more than 4000 cases per year were recorded between 1978 and 1989, 96% of which occurred in “European” republics. Rates in western regions near the Ural Mountains were higher (20–40 per 100,000 population) than were those in eastern districts (2–5 per 100,000 population).²¹⁶ In Korea, approximately 500 persons with HFRS, approximately half of whom are soldiers, are hospitalized annually.²¹⁶ In central and northern Sweden, a mean annual incidence of 4.3 per 100,000 population has been reported, although northern locales have rates of more than 20 per 100,000 population.¹⁹⁸ In Finland between 1995 and 2008, the average annual incidence of Puumala virus infection was 31 per 100,000 population.¹⁴⁸

As of January 2016, 692 cases of HPS had been laboratory confirmed in the United States. Although 30 cases were identified retrospectively, most recognized cases have occurred since 1993.²⁸ HPS is rare in the United States; the annual incidence is estimated to range from 0.04 to 0.19 cases per million persons.¹⁴⁶ Case counts were relatively stable across a 17-year period in the northwestern and midwestern regions of the United States, but greater variability in the southwestern part of the country drove fluctuations in the national HPS case counts.¹⁴⁶ Updated US surveillance data can be found on the Centers for Disease Control and Prevention (CDC) website.²⁸ HPS is less common in Canada, with between 2 and 8 reported cases per year, but more common in South America. More than 4800 cases were documented in South America between 1993 and 2015, with Brazil, Argentina, and Chile reporting most of the cases.

Demographic and Geographic Features

Hantavirus infections are recognized relatively infrequently in the pediatric age group.^{2,5,8,64,107,108,198,216,242} The disease occurs principally in adults, with a significant minority ($\leq 15\%$) of cases diagnosed in children. Reports from Argentina, China, Sweden, and the United States confirm a male predominance in reported incidence of disease,^{92,111,146,147,150} despite serologic evidence that similar proportions of men and women are infected with Puumala virus in Sweden.⁴ In a survey from Finland, 85% of patients were 20 to 64 years old; 62% were male; 52% were hospitalized; 3% were registered as having occupational diseases; and the case-fatality proportion was 0.08%.¹⁴⁸ Case-fatality rates appear to be higher among female patients with HFRS in China (Hantaan and Seoul viruses),¹¹¹ women infected with Andes-associated HPS in Argentina,¹⁵⁰ and women with Puumala virus–associated NE in Sweden.⁹² In all studies, these sex-based differences were most marked among populations at peak reproductive ages (20s and 30s) and older than 50 years.^{92,111,147,149,150} Analysis of US data did not support a similar sex-based difference in case-fatality rates.¹⁴⁷ Interpretations conflict regarding the likelihood that these differences are biologically based. The peak incidence of HFRS in Europe, the Balkans, and the Far East and of HPS in the United States occurs in persons who are 20 to 50 years of age.^{122,128,146,173,219} Few cases have been reported in children younger than 10 years of age. Both HFRS and HPS cases in young children often are recognized in association with cases in other family members.^{8,64,122,161,173,171}

A male predominance has been observed for both the severe (Korean) and milder (European) forms of HFRS in children.^{2,5,115,161,242} Although this pattern, also seen in adults with HFRS and with HPS in the United States, suggests differential susceptibility or risk for exposure by sex, the number of recorded cases, particularly in the youngest age groups, is too small to be used to draw firm conclusions.

In the United States, fewer than 7% of reported HPS cases occur in children younger than 17 years¹⁴⁶; in South America, the proportion of cases in the pediatric age group may be somewhat higher.⁵⁹ The underrepresentation of children recognized to have HFRS and HPS may not be explained by age-related avoidance of activities resulting in exposure. The limited data available (see Clinical Manifestations

below) suggest that hantavirus infections in children may induce milder HFRS and NE syndromes than those seen in adults. In contrast, typical HPS has been repeatedly described in children, particularly teenagers. Comprehensive population-based serosurveys are sparse and have been inadequate to define age-associated infection rates. The apparently immune-mediated pathologic process of hantavirus diseases (see Pathogenesis and Pathology below) is possibly more evident in persons experiencing infection in adulthood.

CLINICAL MANIFESTATIONS

Hemorrhagic Fever With Renal Syndrome

Two major clinical variants of HFRS have been recognized traditionally. Severe disease associated with high morbidity and mortality rates occurs primarily in areas of the world where Hantaan, Dobrava, Saaremaa, and Tula viruses are endemic: across the northern half of Asia, China, the Korean Peninsula, and the Balkan nations. Milder illness with little mortality occurs in areas where Puumala and related viruses have been recovered; this latter disease, a milder variant of HFRS known as NE, is found throughout northern Europe, Scandinavia, and western areas of the former Soviet Union.^{122,123} In the Balkans, the coexistence of Puumala virus-like strains with viruses causing more serious disease has resulted in a mixture of clinical findings in the former Yugoslavia and neighboring countries. Benign manifestations of HFRS are well recognized in many regions where Hantaan virus is found, however, and clinically severe disease occasionally results from Puumala virus infection.^{133,176} Hence, it is important to appreciate the protean nature of this disorder and to recognize the potential for disease of any severity whenever and wherever human infection with hantavirus occurs.

Severe HFRS, such as that associated with Hantaan or Dobrava virus, is a complex, multiphasic disorder that presents substantial challenges to patient management. The clinical course of HFRS caused by Hantaan virus in adults spans a wide spectrum from mildly symptomatic disease to severe hemorrhagic fever and death. Subclinical infections probably occur infrequently.^{242,180} In most cases, the clinical course is relatively benign; severe disease develops in 20% to 30% of patients. Modern-day case-fatality rates range from 2% to 7%. In Korea, approximately one-third of recognized Hantaan virus infections follow a clinical course consisting of progression through five clinically and pathophysiologically defined stages: febrile, hypotensive, oliguric, diuretic, and convalescent.^{129,199} Phases often blur, however, and in milder cases, one or more phases may not be discernible.

After an incubation period of 2 to 3 weeks (range, 4–42 days), most patients report the abrupt onset of high fever, headache, chills, dizziness, myalgia, anorexia, and backache. Approximately one-third of patients experience prodromal mild respiratory or gastrointestinal symptoms. Nausea, vomiting, abdominal pain, and intense thirst may be evident at initial evaluation but increase in severity in succeeding days. Photophobia, blurred vision, and eyeball pain are reported frequently. Physical examination reveals a restless, acutely ill patient with flushing of the face, neck, and upper thoracic region. Relative bradycardia is present. Conjunctival and pharyngeal injection, together with facial puffiness, is characteristic. In more than 90% of patients, petechiae develop on the soft palate, axillae, lateral aspect of the thorax, conjunctivae, or face, generally between the third and sixth days of illness. Tenderness occurs commonly over the costovertebral angles and diffusely throughout the abdomen.

Hematologic studies in the first 3 to 4 days of illness reveal leukocytosis with a left shift in more than 90% of patients, as well as almost universal thrombocytopenia; the hematocrit at this stage generally is normal or slightly increased. Proteinuria develops by the third to fourth day, and microscopic hematuria, hyposthenuria, and mild pyuria are reported in most patients; fibrin clots in urine are characteristic findings.

This febrile phase generally lasts approximately 1 week, followed by abrupt defervescence. Approximately 40% of patients then become hypotensive; in most cases, the drop in blood pressure is mild and brief, but in severely ill persons (30–50% of hypotensive patients), clinical shock develops. Tachycardia replaces bradycardia, the pulse pressure narrows, and cyanosis and mental confusion may be seen. The hypotensive phase may last from a few hours to 3 days, and 30% to 40% of deaths occur during this period.

As patients recover from hypotension, they enter a period of oliguria. This phase occurs in approximately 60% of patients and generally lasts for several days. Anuria develops in approximately 10% of patients. Blood pressure normalizes, and hypertension often develops. Clinical manifestations of uremia, including protracted vomiting and hiccups, may be seen. More extensive hemorrhagic manifestations such as ecchymoses, hemoptysis, hematemesis, melena, gross hematuria, and, rarely, bleeding in the central nervous system (CNS) become evident during the oliguric phase. Striking elevations in blood urea nitrogen and creatinine levels are common findings. Biochemical disturbances (electrolyte derangements, metabolic acidosis, uremia) may be severe, and, in such cases, dialysis may be lifesaving. Approximately one-half of fatalities occur during the oliguric phase.

Between 10 and 14 days into the illness, renal function is restored spontaneously in most patients, and a period of diuresis follows. Polyuria may be substantial, and urine output frequently exceeds 3 to 6 L/day. With the onset of diuresis, clinical recovery is initiated; however, the rapid change in fluid status may precipitate further electrolyte disturbances, so close monitoring remains necessary.

Convalescence typically lasts from 3 to 6 weeks, but in many cases a longer period passes before health is restored completely. Body weight and strength are recovered slowly. Proteinuria resolves, but hyposthenuria persists for months. Most patients recover completely, although permanent sequelae may result from such complications as anterior pituitary or other CNS hemorrhage.

The disease has been reported infrequently in children.^{64,115,242} The data available indicate that clinical manifestations are similar to and perhaps somewhat less severe than those observed in adults. In a series of 63 children identified retrospectively over a 15-year period in Korea, fever was universal, whereas abdominal pain, headache, and vomiting were present in 73% or more of patients (Table 189.2).²⁴² Proteinuria (100%), leukocytosis (71%), thrombocytopenia (80%), hypocholesterolemia (87%), and elevations in creatinine (94%), blood urea nitrogen (94%), and alanine aminotransferase (80%) were the laboratory abnormalities found most commonly. Petechiae and hypotension occurred infrequently (38% and 11%, respectively), and frank hemorrhage occurred rarely. Eleven patients (18%) required dialysis. The mortality rate was 5%, and the remaining patients recovered without sequelae.²⁴²

HFRS occurring in adults after they are infected with Seoul virus resembles that described for Hantaan virus infection, but the clinical manifestations generally are milder.¹²⁹ Fever and constitutional symptoms are similar in the two types of infection, but hypotension occurs infrequently in persons infected with Seoul virus (10% of cases), and clinical shock is a rare event. The frequency and severity of thrombocytopenia are less with Seoul virus infection, whereas elevations of aminotransferases occur commonly (>60% of cases). The mortality rate for HFRS caused by Seoul virus is 1% or less.

Nephropathia Epidemica

The Scandinavian or European form of HFRS (NE) generally is a more benign disease than that attributed to Hantaan virus; fatal outcomes are observed, but the case-fatality rate is less than 1%.⁹⁸ In contrast to the findings with Hantaan virus, subclinical infection apparently occurs commonly with Puumala virus; one report suggested a case-to-infection ratio of 1:10.¹⁶⁷ Host related factors influence severity of disease. In Finland, the most severe disease is more likely to occur in persons with human leukocyte antigen (HLA) alleles B8, C4A-Q0, and DRB1-0301. HLA-B27 predicted a more benign course. In Slovenia, Puumala-infected persons with severe disease were more likely than Dobrava-infected persons with severe disease to have HLA-DRB1-13 haplotype. HLA-B-07 appeared possibly to protect against severe disease following Puumala virus infection. HLA-B-35 was significantly more frequent among Dobrava virus-infected patients than among Puumala virus-infected persons.¹⁶²

In adults, NE is typically described as a biphasic disease of 1 to 3 weeks' duration.^{38,173,228} However, NE resulting from Puumala virus infection has been further divided by some investigators into five phases (febrile, hypotensive, oliguric, polyuric, and convalescent) analogous to prototypical Hantaan infection.¹⁶² The onset of the febrile phase usually is abrupt, with no apparent prodrome. High fever is the initial symptom in 95% of patients. On examination, a facial flush is a usual

finding. This febrile phase lasts from 3 to 6 days. Typical acute febrile phase laboratory abnormalities are anemia, leukocytosis, thrombocytosis, elevated liver function test results and serum creatinine levels, and proteinuria and hematuria.¹⁶²

The development of nausea, vomiting, abdominal pain, back pain, somnolence, and, occasionally, joint pain heralds the onset of the second, or renal, phase. The abdominal pain may be of such severity and character that an acute abdomen is suspected, and many patients have undergone surgical intervention for suspected appendicitis before NE was diagnosed. Visual disturbances are common manifestations ($\approx 43\%$).^{82–84,98} In one prospective study, 70% of patients hospitalized in Finland with acute Puumala infection reported ocular symptoms. Examinations identified decreased intraocular pressure (88%), reduced visual acuity and chemosis (87%), thickening of the lens (82%), myopic shift (78%), and shallowing of the anterior chamber (64%) and of the vitreous length (52%) during the acute phase compared with measurements taken after clinical recovery. That myopic shift was less common than diminished visual acuity suggested that multiple mechanisms, possibly including extraocular CNS involvement, contribute to visual disturbances during acute NE.⁸²

Hypotension, if it develops, usually is mild. Petechiae are seen relatively infrequently (11%).⁹⁸ Severe internal bleeding is rare, seen almost exclusively in adults, and frequently associated with a fatal outcome.⁹⁸ The severity of acute kidney injury does not correlate with hypotension.¹⁶²

The renal stage generally lasts 1 to 2 weeks and is characterized by the subsequent development of an oliguric phase with proteinuria, hematuria, and hyposthenuria. Among hospitalized patients, the decline in glomerular filtration rate can be precipitous.¹⁶² Proteinuria begins abruptly, can be massive, and is nonselective, indicating contributions from both a defective glomerular barrier and from tubular injury.¹⁶² Modest elevations in blood urea nitrogen and creatinine accompany the oliguria, which typically lasts for no more than a few days before diuresis begins (polyuric phase). Mild leukocytosis and thrombocytopenia occur during the renal phase. Electrolyte disturbances sufficient to require dialysis are infrequent events but occur in up to

6% of hospitalized patients.¹⁶² Renal biopsy results reveal histopathologic findings characteristic of acute tubulointerstitial nephritis that correlate with the clinical severity of acute kidney injury but not with the severity of proteinuria.¹⁶²

As with other forms of HFRS, the convalescent phase may be prolonged, and hyposthenuria may persist for many months. With Puumala infection, viremia can last 3 to 4 weeks.¹⁶² Recovery typically is complete, although minor abnormalities in renal function and blood pressure have been described.^{122,165} Hypertension, hypopituitarism, and cardiovascular disease are the most commonly described long-term consequences.¹⁶²

As with Hantaan virus–associated HFRS, NE in children is recognized relatively infrequently. Clinically, the disease also appears to be similar to, although milder than, that seen in adults. Abdominal pain and vomiting are more frequently observed among children than adults, and children are more often hypertensive, thrombocytopenic, and oliguric.⁹⁸ Arthralgias, myalgias, and visual disturbances are more commonly reported in adults, as are epistaxis, leukocytosis, polyuria, and proteinuria.⁹⁸ Results of chest radiographs are more frequently abnormal in pediatric patients.⁹⁸ Among 32 Swedish cases reported (18 identified retrospectively and 14 prospectively), fever (100%), headache (100%), anorexia (100%), abdominal pain (93%), vomiting (91%), nausea (86%), and back pain (76%) were the most prevalent symptoms (see Table 189.2).⁵ Proteinuria (100%), microscopic hematuria (80%), elevated serum creatinine concentration (76%), and thrombocytopenia (68%) were the laboratory abnormalities most frequently found. Leukocytosis was a relatively uncommon finding (22%) in this series. Six children (19%) had hemorrhagic manifestations, and one complained of blurred vision. In a 32-patient series from Finland, fever (100%), nausea (81%), vomiting (72%), and back pain (63%) again were prevalent, but headache and abdominal pain (59%) were reported less frequently.¹⁶¹ Proteinuria (97%), hematuria (73%), and elevated serum creatinine level (84%) were common findings. In a separate 13-patient retrospective series from the same country, abdominal pain was universal

as a presenting symptom, with temperature elevation, oliguria, polyuria, proteinuria, thrombocytopenia, and elevated serum creatinine level ultimately reported in all (see Table 189.2).¹²⁴

Among 19 Austrian children 6 to 18 years old who were identified retrospectively, abdominal pain (100%), fever (89%), nausea (89%), vomiting (84%), and headache (58%) were the most frequent signs and symptoms reported.^{2,5} Ninety-five percent of these children developed acute renal failure, but all appeared to recover fully while under clinical observation. No long-term follow up is available. Thrombocytopenia was reported more prominently among Austrian and Finnish than Swedish children. Up to one-fourth of Austrian and Finnish children displayed hemorrhagic manifestations. The proportion of transient visual blurring was identical to that seen in adults (25%). Some disease manifestations (e.g., thrombocytopenia, renal function abnormalities) may be absent, however, and the disease should be considered in the differential diagnosis of “fever of unknown origin” in endemic areas.²²⁵ Three children with Puumala virus nephropathy in the Czech Republic were admitted with interstitial nephritis after a flulike prodrome. All were mildly febrile and had the following findings: anemia; elevated C-reactive protein values, erythrocyte sedimentation rates, and serum creatinine levels; and proteinuria. Biopsy-confirmed renal abnormalities returned to normal within 4 weeks after corticosteroid treatment.⁵¹ No children in any of these series required dialysis.

Hantavirus Pulmonary Syndrome

Classic HPS in adults is a biphasic illness that challenges the diagnostic acumen and clinical management skills of physicians.^{22,169–171,175} The incubation period was 7 to 39 days (median, 18 days) for 20 people with defined exposure to Andes virus in a high-risk area,²³¹ an observation consistent with the incubation period of 9 to 33 days (median, 14–17 days) for 11 patients with HPS and well-defined exposure in the United States,²⁴³ as well as the 3-week incubation period observed in two boys with HPS who were bitten by the same mouse.²⁰³

The clinical features of the prodrome phase are not pathognomonic; the diagnosis is rarely suspected before abrupt clinical deterioration heralds the onset of the cardiopulmonary phase. HPS characteristically begins with a prodrome that lasts 3 to 4 days but may extend as long as a week or more.^{30,50,138,175,230} This phase is typified by fever and myalgia, particularly of the back or lower extremities. Although a cough may develop as the prodrome progresses, illnesses initially characterized predominantly by upper respiratory tract symptoms, such as cough and coryza, are unlikely to be HPS.^{30,138,151,160} More than one-half of patients with HPS also have gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea) that usually are mild.^{30,50} Occasionally, HPS-associated gastrointestinal symptoms have been mistaken for an acute surgical abdomen or another intraabdominal process. The presence of thrombocytopenia in the context of a compatible prodrome is highly suggestive of HPS.^{30,50,117,160,202}

The onset of the cardiopulmonary phase is abrupt and often life threatening. Patients usually are hospitalized within 12 to 24 hours of initial medical evaluation, and most deaths occur during the first 24 to 48 hours in the hospital.^{30,32,50,138} Among fatal HPS cases identified in the United States between 1993 and 2009, the mean time from onset of symptoms to death was 6.4 days (median, 5 days) and the 35% case-fatality rate was similar across demographic characteristics and geographic regions.¹⁴⁶ Clear lungs shown by radiography have progressed to diffuse bilateral pulmonary involvement during the course of several hours. Interstitial edema, present in only 5% of patients with adult respiratory distress syndrome, is present in most patients with HPS on initial radiography, and alveolar flooding that is usually indistinguishable from the peripheral pattern seen in the acute phase of adult respiratory distress syndrome develops in most patients (Fig. 189.4).¹⁰⁵ This noncardiogenic pulmonary edema, resulting from a diffuse pulmonary capillary leak, can be differentiated from cardiac (hydrostatic) pulmonary edema by the presence of low pulmonary artery occlusion pressure and an increased protein content in edema fluid.⁸⁰ Secretions recovered when patients with HPS are intubated generally are acellular, resemble plasma or pulmonary edema fluid, and have been observed to clot in severe cases.^{50,80} The presence of significant numbers of polymorphonuclear leukocytes in pulmonary secretions suggests an alternative cause.

FIG. 189.4 Anteroposterior chest radiograph reveals the midstaged bilateral pulmonary effusion caused by hantavirus pulmonary syndrome. The radiologic evolution begins with minimal changes of interstitial pulmonary edema and progresses to alveolar edema with severe bilateral involvement. Pleural effusions are common and are often large enough to be evident radiographically. (Courtesy Centers for Disease Control and Prevention and D. Loren Ketaj, MD.)

The pulmonary decline usually is accompanied by the onset of shock caused by myocardial dysfunction and relative hypovolemia.^{30,80,138} In severe cases, hemodynamic measurements show high systemic vascular resistance combined with low cardiac and stroke volume indices. Progression to death is associated with worsening cardiac dysfunction unresponsive to treatment, despite provision of adequate oxygenation.⁸⁰ Increased hematocrit, creatinine levels, and leukocyte counts; requirement for supplemental oxygen; and necessity for intubation are all associated with fatal outcome, and thrombocytopenia, although common, is more pronounced among patients who die compared with survivors.^{30,146} At autopsy, the myocardium of patients who died of Araraquara virus-associated HPS contained endothelial cells and interstitial macrophage-type cells harboring hantavirus antigen and viral particles accompanied by a mononuclear cell inflammatory interstitial infiltrate that met the international consensus criteria for infectious inflammatory myocarditis. These findings were absent from the autopsy myocardium of persons who died after having either necrotizing pancreatitis associated with acute lung injury or nonthoracic trauma.^{183,188} This infectious inflammatory form of cardiomyopathy may be responsible for HPS-associated myocardial depression and shock. In one South American study, the absence of clinical and laboratory signs of circulatory shock on admission was associated with a favorable outcome.¹⁸⁹

Thrombocytopenia may be present in the late prodrome and almost always is found during the cardiopulmonary phase. Additional laboratory abnormalities in hospitalized patients include hemoconcentration, prolonged prothrombin and partial thromboplastin times, elevated serum lactate and serum lactate dehydrogenase concentrations, decreased serum protein concentration, mild leukocytosis with a marked left shift, and the frequent presence of myeloid precursors on the peripheral smear (Fig. 189.5).^{30,50,117,138,175} The left shift and leukocytosis can, on occasion, be so marked as to represent a leukemoid reaction. Proteinuria is a common occurrence. The serum creatinine value often is elevated modestly in severe cases, although renal failure is not characteristic of infection with Sin Nombre virus, despite episodes of hypotension and other predisposing conditions that are present in many patients. Renal failure was more prominent in two reported North American cases of HPS caused by infection with Black Creek Canal virus and Bayou virus.^{86,106,109,185}

Patients who survive enter a diuretic phase after recovery from cardiovascular collapse and improve rapidly thereafter. Surviving patients may be extubated within 3 to 7 days after admission to the intensive care unit and may be discharged from the hospital within 2 weeks.^{30,32,175,188}

Subclinical or mild disease is rarely recognized after Sin Nombre virus infection.²⁰² However, although initial case-fatality rates of 70% to 80% were reported in 1993, a wider clinical spectrum became recognized once clinicians developed heightened suspicion and diagnostic assays

FIG. 189.5 Micrograph shows an atypical enlarged lymphocyte found in the blood smear from a patient with hantavirus pulmonary syndrome. The large atypical lymphocyte shown here is an example of one of the laboratory findings that, when combined with bandemia and a dropping platelet count, is characteristic of hantavirus pulmonary syndrome. (Courtesy Centers for Disease Control and Prevention.)

became more readily available. As of 2011, the overall case-fatality rate for HPS cases in the United States was 35%^{146,147}; case-fatality rates are similar throughout the Americas.¹⁴⁷ This apparent decline in the incidence of mortality compared with initial reports in the early 1990s may reflect improvements in survival attributed to improved clinical management. However, it undoubtedly also reflects a decrease in the tendency to suspect this diagnosis only with the fatal and nearly fatal disease that existed early in the clinical understanding of this syndrome.

The hantavirus disease pulmonary manifestations associated with Andes virus¹⁴³ in Argentina and Chile and those from other related virus infections in Brazil¹⁶³ and Paraguay²³⁶ closely resemble Sin Nombre virus disease. However, hemorrhagic and renal symptoms are more often associated with HPS in South America.^{22,170,184,218,236} Renal failure accompanied some cases in a focus in northern Argentina,¹⁷¹ and both viral antigen and infectious virus have been isolated from urine of Andes virus–infected patients with HPS.⁷⁴ The association of person-to-person transmission with Andes and a few other South American hantavirus infections suggests the need for increased infection control, although some transmission occurs before hospitalization.

HPS is relatively uncommon (7–15% of reported cases) in children younger than 17 years of age. Several case reports and reviews of North American pediatric patients with HPS have indicated that the geographic distribution, clinical course, and mortality rates in children and adolescents are similar to those described for adults.^{8,19,26,108,131,168,182} In South America (predominantly Chile and Argentina), clinical manifestations of HPS in children appear to be similar to those described in North America.^{59,125} Fever, headache, dyspnea or cough, gastrointestinal disturbances, and myalgia are common manifestations in the prodromal phase. Tachypnea and fever are frequent on hospital admission; in one case series, however, hypotension at presentation was an uncommon finding (33%).¹⁸² In one patient, dizziness with an apparent vestibular component was described.¹⁰⁸ Thrombocytopenia, a left shift in the leukocyte differential count, elevated levels of hepatic aminotransferases and lactate dehydrogenase, and hypoalbuminemia typically are noted on admission. Although leukocytosis and hemoconcentration are generally not found early, they may appear later in the course of illness. Investigators suggested that the mortality rate among prepubertal children may be somewhat lower than that seen in older persons,¹⁹ but as patients' numbers have accumulated over time, overall case-fatality rates in pediatric and adolescent patients seem to be similar to those seen in adults (30–40%). In one series, hypotension and the absence of fever at admission were found to be predictive of respiratory failure, whereas elevated prothrombin time (≥ 14 seconds) at admission was predictive of mortality.¹⁸²

The overall mortality rate among 82 children with HPS contracted in Chile was 37%⁵⁹; in one small case series from Argentina, however, the case-fatality rate for HPS in 5- to 11-year-old children was higher

(60%).¹⁷⁷ In the same report the investigators noted evidence of passive hantavirus antibody transfer from a pregnant woman to her fetus, without subsequent illness in the infant. Additionally, a woman who nursed a 7-month-old infant contracted HPS and subsequently died. Hantavirus antibodies were detected to high titer ($>1:6400$) 8 and 15 months later in the infant (who remained healthy), a finding suggesting possible asymptomatic mother-to-child transmission of the infection through breastfeeding.¹⁷⁷

One report suggests that one or more hantaviruses may be infecting children on the Caribbean island of Barbados. Among 272 children younger than 15 years of age who were hospitalized with suspected dengue and who tested negative for dengue but were also tested for hantavirus over a 2-year period, 22% had positive anti-hantavirus immunoglobulin M (IgM) antibody when a commercially available enzyme-linked immunosorbent assay was used. All these children had nonspecific febrile illnesses, with and without accompanying respiratory or gastrointestinal symptoms; four had mild bleeding, but none required intensive care, and there were no fatalities.¹²¹

COMPLICATIONS

In general, human infection with HFRS-associated hantaviruses results in an acute illness with prolonged incapacitation followed by complete recovery. Unless the illness is complicated by organ hemorrhage (e.g., CNS bleeding), long-term sequelae generally have not been observed.

In a Finnish study of 58 hospitalized Puumala virus–infected patients, 87% of these patients had symptoms suggestive of CNS involvement (headache, light sensitivity, nausea or vomiting, or dizziness). Two patients experienced symptoms indicative of encephalitis (vomiting, headache, somnolence, confusion). Two patients experienced an abrupt, complete loss of vision with spontaneous recovery, associated with severe headache, vomiting, dizziness, and pituitary hemorrhage demonstrated by magnetic resonance imaging.⁸⁴ One of the two patients with demonstrated pituitary hemorrhage recovered spontaneously within 3 months.⁸⁴ Young male patients may be at increased risk of developing serious CNS complications during acute Puumala virus infections.⁸³ Epidemiologic associations between previous infections with Seoul virus in the United States and hypertensive renal disease have been reported.^{71,72} In one study, 5 years after recovery, 50% of patients who had HFRS were hypertensive, with a higher glomerular filtration rate and urinary protein excretion compared with 21% of control subjects. These differences resolved by 10 years.¹⁵⁶ These data require further study to determine their significance.

Although prolonged prothrombin and partial thromboplastin times occur commonly among Sin Nombre–infected patients hospitalized in North America, overt disseminated intravascular coagulation and overt hemorrhage are infrequent.^{30,244} Patients with established disseminated intravascular coagulation rarely survive longer than 48 hours. One patient who did survive a cardiopulmonary phase accompanied by overt disseminated intravascular coagulation died 3 weeks later of gangrenous complications.

One 5-year follow-up study of 30 North American HPS survivors (29 infected with Sin Nombre and 1 with Bayou virus) identified proteinuria of more than 150 mg total protein by 24-hour urine collection in more than one-half of the cohort; 17% also had decreased creatinine clearance. Proteinuria prevalence appeared to increase over time and to be associated with increased severity of HPS disease, although treatment by extracorporeal membrane oxygenation (ECMO) may have lowered the risk.¹⁷⁴

The South American HPS-associated viruses have been associated with more extrapulmonary manifestations than have the Sin Nombre infections in the United States. Evidence of disseminated intravascular coagulation, bleeding, and renal manifestations are reported with greater frequency among Andes virus–infected patients.²²

PATHOGENESIS AND PATHOLOGY

In humans, hantaviruses infect alveolar macrophages and follicular dendritic cells, but they primarily target and replicate in endothelium, without apparent cytopathic effect.²⁴⁴ Signs and symptoms of hantavirus

disease are likely the result of both direct effects of the virus on endothelium and the innate and adaptive immune response to infection.²²² Hantaviruses infect human kidney tubular epithelial cells, glomerular endothelial cells, and podocytes, thereby disrupting cell-to-cell contacts, decreasing barrier functions, and causing proteinuria.¹⁶² Barrier breakdown appears to be caused directly by infection and release of cytokines and is not the result of endothelial cell death.¹⁶²

Early clinical events are presumed, and with Andes virus demonstrated, to be accompanied by viremia⁵⁸; however, significant signs and symptoms develop in temporal association with the onset of a measurable antibody response.

In HPS, Andes viral RNA (detected by RT-PCR) has been observed up to 2 weeks before symptom onset.⁵⁸ A statistically significant association has been demonstrated between plasma viral RNA levels at hospital admission and the severity of HPS disease.²³⁷ Survivors rapidly clear virus.²¹⁴

Increased capillary permeability is a hallmark of hantavirus infection, and it appears to be responsible for most of the clinical stigmata observed (e.g., hypotension, extravascular fluid extravasation, pulmonary edema, abdominal pain). Although endothelial cells of small vessels are the primary targets for hantavirus infection, the absence of cytopathic effects suggests that host immune or inflammatory mechanisms are likely principal contributors to capillary leakage.¹⁶² Increased monolayer permeability and loss of integrity of the endothelial cell barrier in association with early increase in secreted vascular endothelial growth factor (VEGF) and concomitant decreased vascular endothelial (VE)-cadherin have been demonstrated during HPS-associated hantavirus infection of human primary lung endothelial cells.^{67,200} VEGF is a potent vascular permeability agent and when present, it binds to vascular endothelial growth factor receptor-2 (VEGFR2), thus initiating the internalization and degradation of VE-cadherin and the disruption of the adherens junctions of the endothelial cell barrier.^{68,200} Virus-induced inactivation of $\beta 3$ integrins and subsequent deregulation of this VEGF/VEGFR2/VE-cadherin cascade is thought to be central to the increase in vascular permeability observed in hantavirus-infected endothelial cells.^{68,76,77,200}

Thrombocytopenia with a nadir of approximately $100 \times 10^8/L$ occurs in most patients with NE approximately 4 to 5 days after the onset of fever and usually resolves within 1 week, although severe thrombocytopenia can predict a severe course of acute kidney failure.¹⁶² The mechanisms underlying thrombocytopenia observed in both HFRS and HPS are not well understood. Decreased platelet count without evidence of decreased function or production is the most common coagulation profile abnormality. Bone marrow biopsy specimens have demonstrated increased megakaryocytes and active platelet function during hantavirus infections. Thus thrombocytopenia may result from increased platelet consumption, and endothelial injury likely contributes to enhanced coagulation, fibrinolysis, and platelet consumption.¹⁶² Cell-associated pathogenic hantaviruses demonstrate direct binding and inactivation of platelets to endothelial cell surfaces by interaction with platelet integrin $\alpha IIb\beta 3$, perhaps contributing to pathogenesis.^{42,68,222} The differential use of $\beta 3$ integrins as receptors by pathogenic hantaviruses is therefore likely relevant to pathogenesis because $\beta 3$ integrins are present on platelets and endothelial cells, and interaction with these proteins can regulate vascular permeability, platelet activation, and adhesion.¹⁴⁷ Bleeding in NE is characteristically mild with petechiae and epistaxis, although hemorrhage has been identified by magnetic resonance imaging and at autopsy and bleeding into multiple organs documented in some cases.¹⁶² Less than 30% of Scandinavian patients with Puumala virus infection have met strict criteria for overt disseminated intravascular coagulation.¹⁶²

Pathologic studies of fatal HFRS cases indicated that multiple organ systems are involved, but a triad of lesions consisting of hemorrhagic necrosis of the renal medulla, anterior pituitary, and cardiac right atrium is described as characteristic.⁹⁷ Magnetic resonance imaging has demonstrated clearly enlarged spleens during acute NE, but the degree of splenic enlargement did not correlate with the degree of thrombocytopenia.¹⁶² Among hospitalized patients with NE, 16% to 35% have abnormal chest radiographs, with pleural effusions, atelectasis, and interstitial infiltrates that correlate with the degree of renal failure, fluid overload, leukocytosis, and thrombocytosis as the most common findings.¹⁶² Endobronchial mucosal biopsy specimens show increased CD8

T cells in epithelium and submucosa, and increased submucosal CD4 T cells, demonstrating a local immune response.¹⁶² Puumala virus antigens are present in lung capillary vascular endothelium of patients with NE as well as in bronchoalveolar lavage fluid.¹⁶² Patients with NE occasionally have myocarditis with nonspecific electrocardiographic changes that may be attributed to acute kidney injury with altered plasma electrolytes and cytokine release, sometimes associated with impaired cardiovascular contraction observed with echocardiography.¹⁶² CNS symptoms are common in Puumala virus infection and include headache, insomnia, somnolence, dizziness, anxiety, and amnesia. About one-half of infected persons who undergo lumbar puncture have elevated IgM, increased protein, or increased leukocytes counts in spinal fluid.¹⁶² Pituitary hemorrhage has been reported during acute HFRS, but recovered patients remain at increased risk of hypopituitarism for reasons unrelated to the severity of HFRS and for which the underlying pathophysiology remains unclear.¹⁶²

In HPS, multiple organ involvement with variable degrees of vascular congestion is noted in all fatal cases. However, the predominant findings at autopsy have involved the lungs, with pulmonary edema and serous effusions seen grossly and interstitial pneumonitis with a mononuclear cell infiltrate, intraalveolar edema, and focal hyaline membrane formation described microscopically (Fig. 189.6). Immunohistochemical studies demonstrated the widespread presence of hantavirus antigens in endothelial cells of the microvasculature, particularly in the lungs, but also in the kidneys, heart, spleen, pancreas, lymph nodes, skeletal muscle, intestine, adrenal gland, adipose tissue, urinary bladder, and brain. However, few histologic changes have been noted in autopsy examination of the kidney, brain, and heart of patients who died of HPS.²⁴⁴

Endothelial cell mRNA responses to infection by pathogenic and nonpathogenic hantaviruses, observed by DNA array analyses, showed differential patterns of gene activation.⁶⁹ Pathogenic Hantaan and New York viruses appeared to suppress early interferon (IFN) responses that were activated by nonpathogenic Prospect Hill virus. Hantaan virus uniquely induced multiple chemokines (interleukin-8 [IL-8], IL-6, growth-regulated oncogene- β [GRO- β]), cell adhesion molecules (intercellular cell adhesion molecule [ICAM]), and complement cascade-associated factors that could play a role in HFRS immunopathogenesis. Although New York virus failed to induce most of the cellular chemokines activated by Hantaan virus, it uniquely induced $\beta 3$ integrin-linked potassium channels, an action that could be important to HPS-induced vascular permeability.^{69,147} Evidence exists that hantaviruses work to subvert host innate immune responses.^{65,211} Hantaviruses use a transcription mechanism that avoids activation of the IFN pathway.^{66,79} Hantavirus Gn and Gc glycoproteins can downregulate the host IFN response and contribute, along with the nucleocapsid protein, to inhibition of the IFN signaling pathway.^{6,137,209} Pathogenic and nonpathogenic hantaviruses both downregulate the IFN induction, but pathogenic hantaviruses do not induce the early IFN responses activated by nonpathogenic hantaviruses described earlier.^{69,147} This difference in innate immune activation has been speculated to contribute to differences in pathogenicity.

Whereas the mechanisms underlying the observed pathologic lesions are incompletely understood, both cellular and humoral immune-mediated mechanisms have been implicated.^{15,39,97,220} Serum antibodies develop within 3 to 7 days of the onset of illness in patients infected with hantaviruses. In patients with HPS, N protein-reactive antibodies are present in serum soon after onset of disease; neutralizing antibodies directed against Gn and Gc glycoproteins follow.^{99,224} High-titer neutralizing antibodies in serum correlate with milder disease, and higher hantavirus-specific IgG levels early in disease are associated with survival.^{12,145}

The abrupt onset of noncardiogenic pulmonary edema in HPS occurs after the development of an immune response directed against viral antigen present throughout the endothelial cells lining the pulmonary capillaries. This temporal association suggests an immune-mediated capillary leak syndrome in addition to direct effects of virus replication and indirect effects of increased VEGF and decreased VE-cadherin on the permeability and integrity of the endothelial cell barrier.^{67,76,77,200}

Virus-specific cytotoxic T lymphocytes have been observed during acute phases of HFRS,⁹⁵ and elevated levels of inflammatory cytokines (IFN- γ , tumor necrosis factor [TNF]- α , TNF- β , IL-6, and IL-10) have been found in sera and renal biopsy specimens of patients.^{95,118,140,212} Animal

FIG. 189.6 (A) Histopathologic features of the lung in hantavirus pulmonary syndrome (HPS), with interstitial pneumonitis and intraalveolar edema. (B) Histopathologic comparison between HPS (*right*) and acute respiratory distress syndrome (*left*). HPS is characterized by interstitial lymphocytic infiltrates and alveolar edema, whereas acute respiratory distress syndrome is characterized by neutrophilic presence and damage to pneumocytes. (Courtesy Centers for Disease Control and Prevention and Dr. Sherif R. Zaki.)

studies have also suggested a role for T-helper cells and antibodies.⁴³ CD4⁺ and CD8⁺ T-cell clones that recognize Hantaan virus N, Gn, and Gc proteins are present in acute and convalescent patient blood samples.^{55,110,215,226,227} Several studies suggest that cytotoxic T lymphocytes play a major role in induction of HPS. Patients with more severe HPS had higher frequencies of Sin Nombre virus–specific CD8⁺ T cells compared with patients with milder disease, and the presence of Sin Nombre virus–specific CD8⁺ T cells has been shown to increase permeability of infected HLA-matched human endothelial cells *in vitro*.^{85,213}

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A high index of suspicion is essential for recognition of hantavirus infection in persons living or traveling in disease-endemic areas and participating in activities that could provide appropriate exposures. The protean nature of the disease in children is such that almost any ill-defined febrile disease (or fever of unknown origin) associated with abdominal or back pain in an appropriate geographic setting should stimulate consideration of the diagnosis, particularly if the clinical syndrome is accompanied by myalgia, if thrombocytopenia or proteinuria is present, or if a history of exposure to rodents or rural environments in disease-endemic areas is elicited.²⁰¹

The differential diagnosis of HFRS includes rickettsial disease, leptospirosis, meningococcemia, other viral diseases, poststreptococcal

syndromes, pyelonephritis, leukemia, and hemolytic uremic syndrome. Differentiating from an acute intraabdominal or pelvic process, such as appendicitis, may be extremely difficult on clinical grounds.

The differential diagnosis of HPS includes rickettsial diseases, leptospirosis, influenza, streptococcal pneumonia, legionellosis, *Yersinia pestis* infection (plague), meningococcemia, brucellosis, mycoplasmal and fungal pneumonias (including *Coccidioides immitis* and *Histoplasma pneumonias*), tularemia, psittacosis, pancreatitis accompanied by adult respiratory distress syndrome, inhalation anthrax, and autoimmune disorders (including thrombotic thrombocytopenia purpura). A prominent cough or sore throat or a localized infiltrate on a chest radiograph that does not generalize within hours argues for a cause other than hantaviral.^{30,32,117,160} A constellation of the absence of a cough in the presence of dizziness, nausea or vomiting, a low platelet count, a low serum bicarbonate level, and an elevated hematocrit discriminated HPS from similar patients with unexplained adult respiratory distress syndrome in two studies.^{30,160} Thrombocytopenia or a falling platelet count provides a valuable clue late in the prodrome. After the onset of pulmonary edema, the presence of four of five findings (thrombocytopenia, myelocytosis, hemoconcentration, lack of significant toxic granulations in neutrophils, and more than 10% of lymphocytes with immunoblastic morphologic findings) has a sensitivity for HPS of 96% and a specificity of 99%.¹¹⁷

Laboratory Studies

Serologic testing remains the mainstay of clinical diagnosis and is widely available through commercial laboratories or, in the United States, state public health laboratories and the CDC. IgM antibodies to nucleocapsid antigen are universally present in symptomatic patients with HPS and almost universally in patients with HFRS; seroconversion takes place up to 5 days after the onset of disease in 2% to 5% of Puumala virus–infected patients with NE.^{90,101,202,223} The extent of viremia, and therefore the utility of testing for viral RNA, varies depending on the infecting hantavirus. Plasma viral RNA correlates with disease severity for both HFRS and HPS, and a high viral load is generally identifiable in the blood circulation of patients with severe HFRS and HPS disease (i.e., infections with Hantaan, Dobrava, Sin Nombre, or Andes viruses).^{90,223} Prospective surveillance of household contact of Andes virus–infected patients with HPS detected hantaviral RNA 5 to 15 days before symptom onset or detection of IgM antibodies.²²³ Although the viremia level is lower in Puumala virus–associated NE cases, viral RNA detection may be successful on blood samples collected within the first 7 days after symptom onset.²²³ Detection of viral RNA in urine or cerebrospinal fluid of hantavirus-infected patients helps describe pathophysiology but has little diagnostic utility, although detection of hantavirus RNA in saliva may prove useful for diagnostic applications.²²³ Kidney biopsies were used for diagnosis of HFRS in earlier years, but findings were generally nonspecific; interstitial hemorrhage was found in only 25% of HFRS cases, and identification of viral markers was rare.²²³

Routine immunohistologic methods can detect hantavirus antigens in autopsy samples.²²³ Laboratory diagnosis of HFRS or HPS is made by demonstrating specific anti-hantavirus IgM antibodies in acute-phase serum by enzyme immunoassay in the IgM capture format. A fourfold or greater rise in specific IgG antibodies by enzyme immunoassay or immunofluorescence^{120,136} in sequential sera (ideally obtained ≥ 2 weeks apart) also is useful. The availability of purified recombinant hantavirus antigens has enhanced diagnostic specificity in both the enzyme immunoassay and the Western blot assay systems.^{57,99,101,223,248} Enzyme-linked immunosorbent assay and indirect fluorescent antibody tests are broadly cross reactive, particularly among viruses from rodents of the same subfamily.^{35,36} For example, a recombinant Sin Nombre virus antigen detects antibodies against Bayou, Black Creek Canal, Andes, and several other viruses from sigmodontine and neotomine rodents, and it maintains reactivity with antibodies directed against arvicoline rodent-associated viruses (e.g., Puumala and Prospect Hill viruses). Neutralizing antibody assays are more specific, but technical requirements preclude their routine use.^{101,223} Immunohistochemical techniques have been applied to tissue samples from patients infected with hantaviruses.^{244,223} Nucleic acid primers from several hantavirus strains have been generated, and they have enabled nucleotide sequences from

fresh or frozen tissues to be amplified by RT-PCR. RT-PCR usually is successful on whole blood or blood clots obtained within the first 7 to 10 days of illness. However, the expense and effort of performing the method are not justified unless the resulting genetic sequence information is needed for definition of the viral strain or for epidemiologic studies.^{7,164} Attempts to isolate hantaviruses from human specimens are generally unrewarding.

TREATMENT

Cautious fluid management and hemodynamic management in an intensive care unit setting are the most important aspects of the clinical management of any hantavirus disease.^{138,80} Early hospitalization and avoidance of even minor trauma are essential to maintain the integrity of damaged vascular beds in these patients. Transport of patients should be minimized; the barotrauma associated with transport in underpressurized aircraft may be particularly hazardous.¹⁸ Attention to fluid management and metabolic status is especially critical.

In patients with HFRS, restriction of fluids may be necessary early in the course of disease as renal function diminishes, but large input may be required later during diuresis to correct massive losses. Electrolyte abnormalities and metabolic acidosis occur commonly. Peritoneal dialysis or hemodialysis may be lifesaving in severe cases.¹⁸

In patients with HPS, the nature of the pulmonary disease predisposes to iatrogenic pulmonary edema; careful attention must be paid to maintaining appropriate central venous and pulmonary arterial pressure to avoid such complications. Tissue perfusion and adequate oxygenation are the goals of supportive therapy with this syndrome. Oxygen supplementation and mechanical ventilation are nearly always required. Inotropic agents may be necessary to maintain tissue perfusion.^{80,138} ECMO has been used in severe HPS cases; some studies suggest that this procedure may improve survival.^{41,45} One study suggested that ECMO may also be associated with a lower risk of proteinuria after acute disease.⁷⁴

Studies have suggested that cytotoxic T-lymphocyte activity and other aspects of the inflammatory response contribute to the capillary leakage observed in patients with HFRS or HPS, and case reports have attributed clinical improvement to treatment with corticosteroids and venovenous hemodiafiltration.^{85,197} Immunotherapeutic approaches that may inhibit the vascular permeability induced by hantavirus infection were under clinical investigation in 2011.¹⁴⁷

Hantaan, Sin Nombre, and several Old and New World hantaviruses exhibit similar *in vitro* sensitivity to ribavirin. One prospective, placebo-controlled trial suggested that intravenous ribavirin was effective in reducing the mortality and morbidity rates associated with HFRS in China.⁹⁶ In contrast, although 30 patients with HPS who received investigational, open-label intravenous ribavirin generally tolerated it well, treatment was accompanied by a low frequency of early drug-associated adverse events, most significantly anemia and resulting transfusion, and no clear evidence of benefit was obtained.^{30,32} A subsequent randomized placebo-controlled trial was stopped short of a definitive end point because of small enrollment without trends supporting either efficacy or adverse events.¹⁵⁵ However, the study sample size was insufficient to exclude adverse events that occurred at a rate of less than 27%.¹⁴⁹ Similar doses of intravenous ribavirin resulted in hemolysis in 76%, a 2 g/dL hemoglobin level decrease in 49%, and discontinuation because of toxicity in 18% of 126 patients treated for severe acute respiratory syndrome, findings consistent with observations during the open-label trial.^{14,30,32,149} This contrast in clinical experience is not explained by differences in dosing schedules; patients in all three protocols received identical doses.^{14,32,96} Because all hantaviruses have been sensitive to the antiviral effects of ribavirin *in vitro*, the lack of any dramatic effect by intravenous ribavirin in HPS is probably the result of the rapid progression of the disease; HPS-associated deaths usually occur within the first 48 hours after admission and therapeutic intervention.^{30–32,50,80,96,138} Although ribavirin administered at 3 days after infection provided complete protection from disease in a hamster animal model,¹⁸⁷ the 2- to 3-week incubation period associated with Andes and Sin Nombre-virus infections leading to HPS precludes administration of ribavirin comparably early in human infection.

Administration of 5000 or more neutralizing antibody units (NAU) of an HPS survivor per kilogram or of 12,000 NAU/kg of a despeciated (Fc removed) polyclonal immunoglobulin-based product purified from the eggs of ducks vaccinated with a DNA vaccine protected against lethal disease when given up to 8 days after intranasal Andes virus challenge in the same hamster model.¹⁶ Therapeutic approaches attempting to combine ribavirin with other therapeutic agents, including immune modulators, may be more efficacious. Ribavirin is not licensed for intravenous use in the United States. Teratogenic concerns mandate careful informed consent if the use of this drug is considered in children, pregnant women, or nursing mothers. A single case report of a patient with severe NE suggested that treatment with a synthetic polypeptide licensed for treatment of hereditary angioedema, icatibant, may have improved survival.¹⁶²

PREVENTION

Primary Prevention

The most effective preventive measure available for hantavirus infection is the avoidance of rodents and their habitats. However, eradication of rodent reservoir hosts in disease-endemic areas is not feasible. Prevention efforts are directed more appropriately toward reducing the frequency of rodent-human interactions through environmental hygiene practices that minimize rodent abundance in home and work environments and avoidance of known rodent-infested areas and activities that increase the risk of human exposure to aerosolized infectious rodent excreta. Such avoidance may be particularly important during times of high rodent populations in specific localities.

In the United States hantavirus infection is a nationally notifiable condition reported to state health departments, who notify the federal public health agency, the CDC.⁴⁰ In the southwestern United States remote sensing patterns from the year before have predicted local areas of increased risk for HPS, thus allowing precisely targeted public health messages and interventions.⁷⁰

Detailed guidelines on measures appropriate to eliminate rodents from homes in disease-endemic areas, to clean rodent-contaminated areas safely, and to minimize the risk for workers occupationally exposed to rodents and participants in outdoor recreational activities have been published.¹⁵⁸ Although rodent ectoparasites do not transmit hantaviruses, in the southwestern United States, several rodent species are also hosts to fleas that transmit *Yersinia pestis*. In such areas, insecticides should be used in conjunction with rodent extermination measures because eradication of rodents without concurrent control of the associated fleas may increase the risk of human plague.¹⁵⁸

One study²²⁹ reported a strong association between smoking and infection with Puumala virus, but more study is needed to demonstrate cause and effect. As these authors hypothesized, one potential mechanism would be that smoking impairs respiratory ciliary action, thereby increasing the likelihood that Puumala virus in an aerosol exposure would reach the alveoli and remain long enough to cause an infection.

Vaccine Prospects

Both rodent brain-derived and cell culture-derived inactivated vaccines to Hantaan and Seoul viruses have been developed in South Korea and China. Some of these vaccines induce neutralizing antibody responses in humans and are being tested in field studies, but none has been approved in the United States.^{172,190,205,206} A commercial suckling mouse brain-derived vaccine marketed in Korea, Hantavax, has no reported safety issues but placebo-controlled trials have not been conducted, and a case-control study did not have sufficient statistical power to demonstrate efficacy.¹⁸⁹ Monovalent and bivalent cell culture-based Hantaan virus- and Seoul virus-inactivated vaccines produced in China elicited neutralizing antibodies in more than 90% of persons tested who received three doses.¹⁹⁰

A recombinant vaccinia strain expressing Hantaan virus antigens has been tested in human volunteers in the United States and has been shown to induce a serum neutralizing antibody response.¹⁹³ However, because only 26% of vaccinia virus-immune volunteers developed neutralizing

antibodies, this vaccine has not been pursued.¹⁹⁰ A plasmid DNA platform vaccine delivered by gene gun was developed because the platform allows ready construction of combination vaccines and because the absence of a protein component means that preexisting vector immunity is not a problem. DNA vaccines for Hantaan and Puumala viruses have been developed, tested in animals, and moved into phase I clinical trials.¹⁹⁰ Various other approaches to vaccine development against hantaviruses across the globe are under way,^{17,119,139,141,152,247} but none have progressed to clinically relevant interventions. An immediate need exists for a vaccine to Hantaan virus and perhaps other hantaviruses, but until recently a lack of realistic animal models of human disease hampered efforts to perform full preclinical evaluation of candidates. This is particularly important because the diseases are immunopathologic, and some monoclonal antibodies can enhance macrophage infection in vitro. The discovery that hamsters infected with Andes virus provide a reproducible model for HPS that mimics the human disease very closely⁹³ provides an avenue to explore mechanisms of disease and also vastly improves preclinical evaluation of hantavirus vaccine candidates. Nonetheless, even more than with other viral vaccines, double-blind, placebo-controlled trials are needed to provide definitive evidence of protection and to exclude adverse effects.

Hospital Infection Control

The use of universal precautions in handling the blood and body fluids of all patients is prudent practice. In addition, a certified biologic safety cabinet should be used for all handling of human body fluids in situations in which splatter or aerosolization is possible.^{23,27} Viral antigens can be detected in necropsy specimens, and RT-PCR readily detects viral genetic material in necropsy tissue and in blood and plasma obtained from hantavirus-infected persons early in the course of the disease.^{89,244} However, secondary transmission of hantaviruses associated with HFRS has not been documented after contact with acutely ill persons or exposure to their clinical laboratory specimens.²²¹ The experience with North American hantaviruses linked to HPS has been similar.²³³

In contrast, a well-documented episode of person-to-person spread during an Andes virus outbreak in South America and subsequent molecular and epidemiologic studies have demonstrated numerous occurrences of person-to-person transmission of Andes virus.

Person-to-person spread has been reported to result in secondary cases among up to 3.4% of household contacts of primary HPS cases, with sexual partners at greatest risk.^{56,58,125,151,170,218,235} With the possible exception of Andes virus infections, the many years of experience with HFRS and HPS indicate that once the diagnosis has been confirmed, isolation of hospitalized patients to prevent nosocomial transmission generally is not required. In plague-endemic areas, respiratory isolation pending confirmation of hantavirus infection may be a wise precaution. Sera and other specimens from hantavirus-infected persons can be handled safely by using biosafety level 2 facilities and practices. Higher biosafety levels are recommended for attempts to propagate hantaviruses.²⁷

La Crosse Encephalitis and Other California Serogroup Viruses

W. Garrett Hunt • James E. McJunkin

La Crosse virus (LACV) is a member of the California serogroup viruses within the family Bunyaviridae and the genus *Orthobunyavirus*. The term *California serogroup* does not describe the widespread geographic distribution of viruses in the serogroup but simply reflects the name of the prototype virus, California encephalitis virus (CEV), initially discovered in California in 1943.⁶⁷ LACV, the most prevalent and pathogenic member of the serogroup, causes disease in the upper Midwestern, mid-Atlantic, and southeastern United States, particularly in Appalachia in more recent reports, but not on the West Coast (Figs. 190.1 and 190.2).^{20,55,59,64,93,99,124,144,145} LACV is estimated to cause 8% to 30% of all cases of encephalitis in the United States annually, and in 2011, LACV was the most common arboviral infection of children in North America, a finding consistent with previous reports.^{26,27,126} In 2014, there were 80 cases of LACV disease reported from 9 states, with 72 cases in persons younger than 18 years old and 76 cases of neuroinvasive disease.⁹⁵ From 2003 to 2012, LACV neuroinvasive disease was reported from 204 counties in 21 states. The average annual incidence in children was 0.090 cases per 100,000 children (range, 0.053–0.151 cases), compared with the rate in adults, 0.004 per 100,000 adults.⁴⁹ In

a separate analysis, the average annual reported incidence of neuroinvasive disease (meningitis, encephalitis, and meningoencephalitis) caused by the California serogroup viruses as a whole from 1999 to 2007 was 0.035 case per 100,000 population per year (all those patients in whom the etiology was tested had confirmed or probable California serogroup-associated disease).¹²⁴

The medical, psychosocial, and economic costs to affected persons in endemic areas are significant. Acute morbidity includes seizures in roughly 50% to 60% of hospitalized cases, mental status changes in one- to two-thirds, cerebral edema in 16%, and cerebral herniation in 2% to 3%. Approximately 9% to 25% of all hospitalized patients require mechanical ventilation.^{101,106} Long-term morbidity after severe disease may include cognitive delays in up to one-third and attention-deficit/hyperactivity disorder in up to two-thirds of all patients.¹⁰¹ The mortality rate of LACV encephalitis (LACVE) is relatively low compared with that of certain other arboviral illnesses, such as West Nile virus (WNV) infection or eastern equine encephalitis. However, the first risk assessment mapping of LACVE cases, reported to the Centers for Disease Control and Prevention (CDC) from 2003 to 2007, found a mortality rate

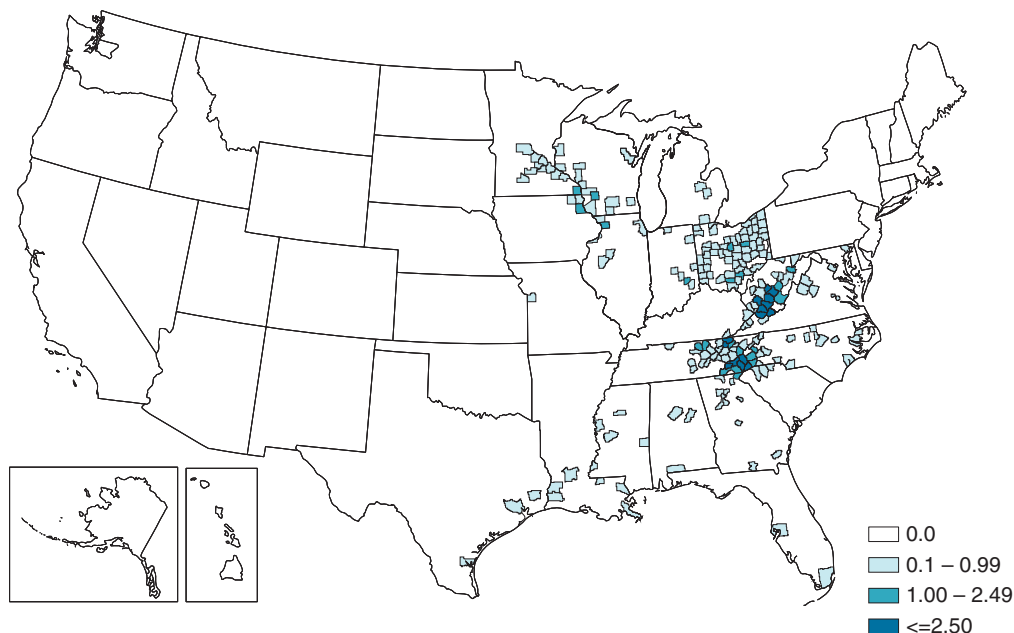

FIG. 190.1 La Crosse virus neuroinvasive disease average annual incidence by county, 2004–13. (Modified from ArboNET, Arboviral Diseases Branch, Centers for Disease Control and Prevention.)

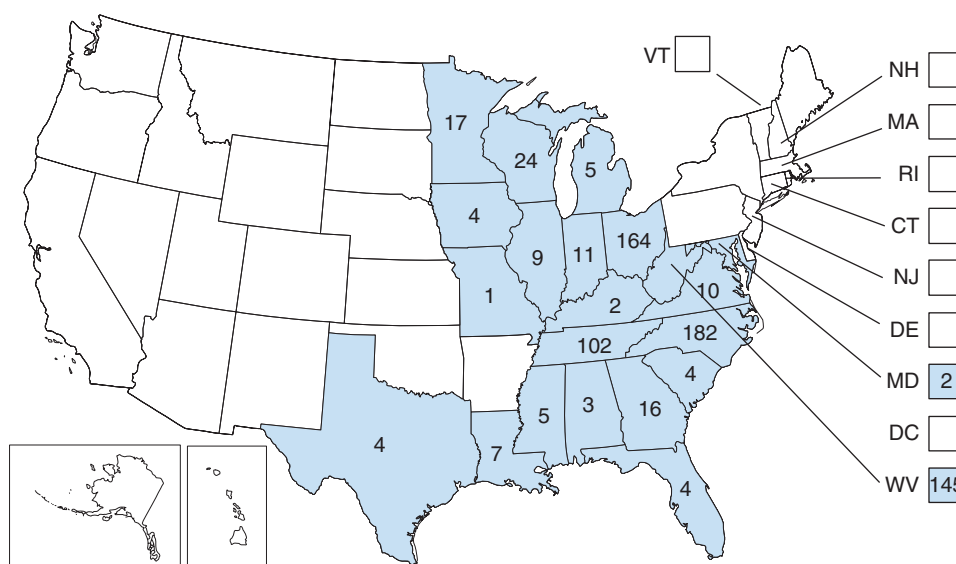

FIG. 190.2 La Crosse virus neuroinvasive disease cases reported by state, 2004–13. (From ArboNET, Arboviral Diseases Branch, Centers for Disease Control and Prevention.)

of 1.9% among confirmed cases, higher than previously reported (0.3%).^{64,124,126} In a study of the economic and social impact of LACVE in an endemic region of western North Carolina, the average direct and indirect medical costs per patient (from a group of 24 patients studied over 89.6 life-years) were roughly \$33,000 (\leq \$35,000). The projected cost for five patients with neurologic sequelae ranged from approximately \$50,000 to \$3 million per patient.¹⁴⁷ Although the number of confirmed cases of LACV-associated neuroinvasive disease in the United States is usually 80 to 100 per year, with an approximate range of 30 to 170 per year from 1964 to 2014, underrecognition and underreporting within a voluntary national reporting system are common problems (Fig. 190.3).^{93,95} Because LACV is the most clinically significant member of the California serogroup viruses, it is the focus of this chapter, but other members of the serogroup are addressed briefly.

ETIOLOGIC AGENT

In 1960, a 4-year-old girl died of “rural encephalitis” in a hospital in La Crosse County, Wisconsin. In 1965, Thompson and colleagues^{141,143} reported the isolation of a novel virus from frozen homogenates of the child’s brain by intracerebral inoculation of suckling mice. Soon after its discovery, LACV was identified as a member of the California serogroup viruses on the basis of complement fixation and virus neutralization tests; it is one of five such viruses causing human disease in North America.

The prototype, CEV, is 1 of 16 viruses in the *Orthobunyavirus* genus. CEV was discovered in mosquitoes from Kern County in the San Joaquin Valley of California in 1943 and linked to human cases of encephalitis in the same region in 1945.^{66,67} The other four viruses of this serogroup

FIG. 190.3 La Crosse virus neuroinvasive disease cases reported by year, 2004–13. (From ArboNET, Arboviral Diseases Branch, Centers for Disease Control and Prevention.)

in North America include LACV, snowshoe hare virus (SSHV), Jamestown Canyon virus (JCV), and trivittatus virus (TV). Inkoo virus (INKV) and Tahyna virus (TAHV) are members of the California serogroup viruses distributed in Europe.

The LACV virion is pleomorphic, roughly 90 to 100 nm in diameter, and has a host-derived viral envelope with virus-encoded glycoproteins, Gc (formerly G1) and Gn (formerly G2), located on spikes 5 to 10 nm long. The virus replicates in the cytoplasm and buds from the Golgi apparatus. Of the three segments of the RNA genome, the large (L) RNA segment encodes the polymerase, the medium (M) RNA segment encodes the Gc and Gn glycoproteins and a nonstructural protein (NSm), and the small (S) RNA segment encodes the nucleocapsid (N) protein and nonstructural protein NSs.^{15,121}

The M segment that encodes the Gc and Gn glycoproteins is a major determinant of viral neuroinvasiveness in mice and susceptibility of *Ochlerotatus triseriatus* (formerly known as *Aedes triseriatus*) mosquitoes to oral and intrathoracic infection.^{53,55,128} Neuroinvasiveness may be linked to the cell receptor and fusion functions associated with glycoproteins.^{53,54} The Gc protein of LACV is involved in viral attachment to mammalian cell receptors, by functioning as a type II fusion protein,^{120,121} and is involved in hemagglutination and viral neutralization.^{53,55,86,87,128} Group- and LACV-specific epitopes are present on Gc. Gc is also required for infection of mosquito cells in vitro and in vivo.⁶³ The Gn glycoprotein mediates viral attachment to insect cells.³⁶ Whereas the M segment genome has been defined in great detail in terms of its neuroinvasiveness, that is, the ability to invade the central nervous system (CNS) from an extraneural site, through its glycoprotein products Gc and Gn, viral reassortants have implicated the L segment as a major factor in determining neurovirulence, which is the ability to cause CNS disease after direct cerebral injection.^{58,132} Furthermore, studies of Gc fusion peptide mutants have shown significantly reduced replication but a persisting ability to cause neuronal death in culture, findings implicating the native Gc fusion protein as important in neuroinvasion but not necessarily in neurovirulence.¹³² Finally, a viral component encoded by the S segment also seems to serve a role in pathogenesis. NSs was shown in insect and mammalian cells to inhibit the RNA interference pathway, thus interfering with a mechanism of innate immune response to viral infection. NSs has also been shown to be involved in apoptosis, the main mechanism by which LACV causes cell death.^{15,131} Investigators have shown that a truncated Gc protein preparation induces a protective immune response in suckling mice through neutralizing antibody (see [Prevention](#)).¹¹⁶ Apparently, neutralizing antibody can prevent neuroinvasion by interruption of transient viremia, which occurs just after virus inoculation. A study by Taylor and colleagues¹³⁹ found that the myeloid dendritic cell, an early response cell type, was critical to protect adult animals and that this cell type was

reduced in young animals. Activation of the myeloid dendritic cell line during virus infection or after treatment with type I interferon in young animals provided protection from LACV neuroinvasion.¹³⁹ This finding may help to explain the preponderance of pediatric versus adult cases of LACV.^{138,139}

Oligonucleotide maps of LACV isolates from various areas of the United States have grouped the viruses into three types. Upper Midwest viral strains are of two types, A and B, and type C varieties are found in scattered areas of the eastern part of the United States.^{45,89} Variations in strains indicate that changes in the viral genome occur by genetic drift. Genetic reassortment through exchange of RNA segments also has been demonstrated in nature; one proposed mechanism involves dually infected mosquitoes, particularly those mosquitoes with initial transovarial infection preceding superinfection with a second closely related virus.¹⁶

ECOLOGY

La Crosse Virus

Borucki and coworkers¹⁷ provided an in-depth review of LACV replication in vertebrate and invertebrate hosts. *O. triseriatus*, the eastern tree hole mosquito, is the reservoir of LACV in nature and the vector for transmission of infection to humans ([Fig. 190.4](#)).^{59,101,149,150} Humans do not maintain prolonged viremia and therefore are dead-end hosts. The mosquito is distributed principally in eastern hardwood deciduous forests, where it breeds in tree holes; however, it also is adapted to breeding in small artificial containers that hold rainwater, such as discarded cans, bottles, and tires. The mosquito is diurnal (i.e., it feeds actively during the day). Although these insects disperse over a wide area, fairly permanent foci of infected mosquitoes are observed in sharply delimited areas, and both isolation of virus and detection of human cases recur in established foci each summer.^{9,59,88,136}

The most important mechanism for maintenance of LACV in nature is vertical (transovarial) transmission in *O. triseriatus*. The virus overwinters in infected eggs, which give rise to infected mosquito progeny the following year, thereby providing the mechanism of recurrent disease each summer in endemic areas.^{107,135,150} Transovarial transmission of LACV in *O. triseriatus* is controlled by a single gene locus.⁵⁷ LACV also is maintained in nature through horizontal transmission by venereal propagation in *O. triseriatus* and through amplification of the virus in the vertebrate hosts on which vector mosquitoes feed.^{107,149,150} Vector competence, related in part to the ability of the female mosquito to become infected in the first place (only female mosquitoes take blood meals), may be associated with malnutrition of the mosquito, which compromises its mesenteric barrier and allows infection to occur after the mosquito takes an LACV-infected blood meal.^{57,114} The principal amplifying hosts involved in horizontal transmission are chipmunks and squirrels, specifically the eastern chipmunk, *Tamias striatus*, the gray squirrel, *Sciurus carolinensis*, and the fox squirrel, *Sciurus niger*.^{91,110,156} Other wild vertebrates, such as foxes and woodchucks, may contribute to amplification. Although domestic livestock and pets are thought not to contribute to horizontal amplification of the virus, certain species do show seroconversion to California serogroup viruses, and these species may prove to be useful markers of viral presence in a given area.⁵² Concern that *Aedes albopictus*, the Asian tiger mosquito, has entered the transmission cycle for LACV was heightened in 2001 when LACV-infected *A. albopictus* mosquitoes were isolated in nature in areas proximate to human cases.^{7,8,34,35,51,60,75} In addition, an elevated burden of *A. albopictus* near the residence of patients with LACV was associated significantly with LACV infection in cases versus controls.⁴⁷ This mosquito species, which was first discovered in the United States in 1985 in Houston, Texas, has since dispersed widely throughout the southeastern United States. The presence of LACV in *A. albopictus* mosquitoes in Dallas County, Texas, in the late summer of 2009 signified the possible expansion of the geographic range of LACV within this invasive mosquito species in Texas.⁹³ *A. albopictus* has significant further potential to expand the geographic range and frequency of transmission of LACV and possibly other California serogroup viruses. Most recently, another mosquito vector, *Aedes japonicas*, has been identified.^{69,151}

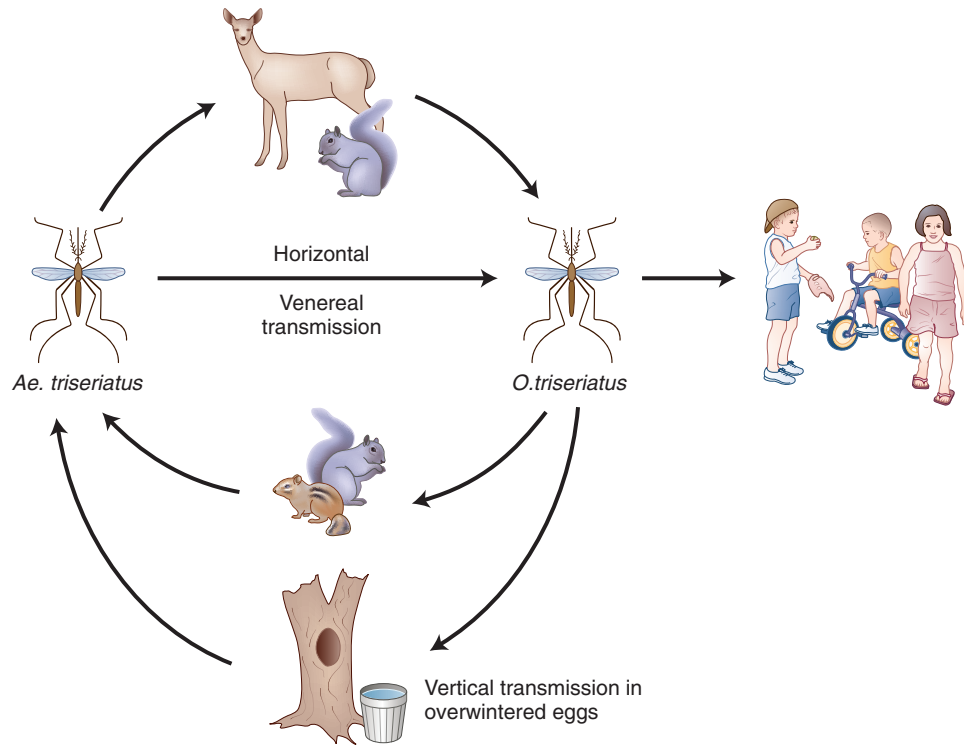

FIG. 190.4 La Crosse virus transmission cycle. The virus is maintained by vertical transmission in *Ochlerotatus triseriatus* mosquitoes; the virus overwinters in infected eggs that usually are deposited in tree holes or in artificial containers holding rainwater. Horizontal transmission by viral amplification in small vertebrates, such as squirrels and chipmunks, or by the venereal route, among adult mosquitoes, is required to supplement vertical transmission. The role of deer in viral amplification is uncertain. Human infections are incidental to the transmission cycle. (From McJunkin JE, Khan RR, Tsai TF. California—La Crosse encephalitis. *Infect Dis Clin North Am.* 1998;12:83–93.)

Other California Serogroup Viruses

A brief discussion of the ecology of other California serogroup viruses follows. Although JCV was isolated first in Colorado and is distributed widely in the West and Midwest, most cases of human illness have been reported in New York, New England, Ontario, and the upper Midwest. Seroconversion to JCV also has been found frequently (18%) in native Alaskans.¹⁴⁸ Various *Aedes* mosquitoes, including *Aedes communis* in the West, *Aedes stimulans* in the upper Midwest, and *Aedes abserratus* in Connecticut, function as vectors.^{37,59,60,61} As opposed to LACV, for which large mammals do not play a role in viral propagation in nature, the horizontal amplification of JCV includes deer as the primary amplifying host, with up to 80% seroconversion found in adult deer populations in endemic areas.^{112,113,157} The overwintering mechanism of JCV has not been elucidated, although transovarial transmission in *Aedes provocans* has been demonstrated.¹⁴

SSHV is distributed throughout Canada, including the Yukon and Northwest Territories, and in Russia and China. *Culiseta inornata* and various *Aedes* spp. transmit the virus to snowshoe hares (*Lepus americanus*), ground squirrels (*Citellus undulatus*), and other mammals. Transovarial transmission in vector mosquitoes has been demonstrated.⁷⁰

TV is transmitted and maintained through vertical transmission by *Aedes trivittatus* in the Midwest and by *Aedes infirmatus* in the South. CEV is distributed in the western part of the United States, where *Aedes melanimon* and *Aedes dorsalis* are the principal vectors.^{57,66,122,142}

INKV and TAHV cause a febrile illness typified by CNS or respiratory tract symptoms, respectively, within the same regions: Scandinavia, central Europe, and western Russia. INKV also has been found in native Alaskans,¹⁴⁸ whereas TAHV has additional endemicity in Asia and Africa.^{58,65} Viral recombinants of these viruses have been demonstrated.³⁸

EPIDEMIOLOGY

LACV-associated neuroinvasive disease occurs principally in children. From 2003 to 2012, 754 cases of neuroinvasive disease caused by LACV

were reported from 204 counties in 21 states within the United States, and 88% (665, including five reported as unspecified California serogroup virus) of all cases occurred in persons younger than 18 years of age.⁴⁹ Of the 665 pediatric cases, 412 (62%) occurred in boys. The median age of patients was 7 years (range, 1 month–17 years), and 309 (46%) were 5 to 9 years of age. The average annual incidence in children (persons <18 years) reported to the CDC was 0.09 per 100,000 children per year (range, 0.053–0.151 cases).⁴⁹ LACV infections are endemic in the United States, typically occurring from July through October and mainly in rural areas of the east-central states.^{84,144} In CDC data from 2003 to 2012, 544 cases (82%) of LACV-associated neuroinvasive disease in children occurred from July through September, but 8% occurred in June and October, respectively.⁴⁹ The medical and economic burden to affected persons and society in endemic areas is significant.¹⁴⁷ Table 190.1 summarizes demographic data and clinical characteristics for a large series of hospitalized children.¹⁰¹

The geographic distribution of LACV infection corresponds to natural divisions in which beech, oak, and maple woodlots are prevalent.⁵⁹ Although LACV has been considered a disease of the Midwestern and mid-Atlantic states (with highly endemic zones along the upper Mississippi River Valley, specifically in Minnesota, Wisconsin, Illinois, and Iowa, and in Appalachia, particularly in Ohio and West Virginia), cases were reported in 21 states from 2004 to 2013, mostly east of the Mississippi River (see Fig. 190.2). From 2003 to 2012, the four states with the highest average annual incidence rates of LACV-associated neuroinvasive disease and 81% of cases were the following: (1) West Virginia (3.769 per 100,000 children and 146 cases); (2) Tennessee (0.628 per 100,000 children and 94 cases); (3) North Carolina (0.622 per 100,000 children and 142 cases); and (4) Ohio (0.586 per 100,000 children and 160 cases).⁴⁹ One highly endemic focus has been recognized in western North Carolina for many years,¹³⁵ and sporadic cases have been found as far south as Louisiana and as far east as Connecticut (see Fig. 190.2). Although certain foci of infection appear to remain well localized,^{108,135} investigations in eastern Tennessee showed a low seroprevalence in the

TABLE 190.1 Epidemiologic and Clinical Data of 127 Children With La Crosse Encephalitis^a

Variable	Value
Sex: No. (%)	
Male	90 (71)
Female	37 (29)
Age in Years: No. (%)	
0.5–2	9 (7)
3–5	30 (24)
6–8	42 (33)
9–11	26 (20)
12–14	19 (15)
15	1 (1)
Month of Presentation: No. (%)	
June	3 (2)
July	31 (24)
August	38 (30)
September	44 (35)
October	11 (9)
Symptoms on Presentation: No. With Findings/ Total No. (%)^b	
Headache	105/126 (83)
Fever	107/125 (86)
Vomiting	89/127 (70)
Disorientation	50/119 (42)
Seizures ^c	58/127 (46)
Signs on Admission: No. With Finding/Total No. (%)	
Nuchal rigidity	31/120 (26)
Glasgow Coma Scale score ≤ 12	42/127 (33)
Focal neurologic signs	23/126 (18)

^aFor symptoms on presentation and signs on admission, data were missing for some patients. Because of rounding, not all percentages total 100.

^bTypically, the patients with headache or fever were admitted 3 or 4 days after presentation; those with vomiting were admitted 1 or 2 days after presentation; and those with disorientation or seizures were admitted on the day of presentation.

^cSeizures were generalized in 22 patients, partial in 24, and partial with secondary generalization in 22.

Data from McJunkin JE, de los Reyes EC, Irazuzta JE, et al. La Crosse encephalitis in children. *N Engl J Med*. 2001;344:801–807.

general population (only 0.5%) despite a recent marked increase in the number of pediatric cases in that region, a finding suggesting that true increases in the incidence of LACV infection (indicating a newly established endemic focus) do occur in some areas.^{81,82} For true increases of case incidence to be detected, it may be necessary to track cases at a county level as opposed to a state level. The variability of case incidence within a state is apparent in CDC county incidence data, for which the county incidence varied from 0.2 to 228.7 cases per 100,000 persons, with both confirmed and probable cases combined (see Fig. 190.1). Therefore a wide variation results from the focal nature of the virus among counties reporting LACV infections, and this phenomenon highlights the need to report the range of incidence risk in relatively smaller zones (e.g., county) rather than only the mean incidence risk (e.g., state), which may not provide an accurate assessment of risk within focal areas.⁶⁴

Most LACV infections are asymptomatic. Clinical disease ranges from mild illness with or without fever to severe encephalitis. For the purposes of surveillance and reporting, cases of LACV-associated clinical disease, like all cases of arboviral disease, are often categorized as either neuroinvasive (meningitis, encephalitis, or meningoencephalitis) or nonneuroinvasive. Signs of central and peripheral neurologic function are included in the clinical criteria for neuroinvasive disease. Although lower motor neuron disease such as acute flaccid paralysis is included as a part of the clinical criteria, this finding is much more pathognomonic of disease caused by WNV than LACV. LACVE is, however, associated

with acute hemiparesis secondary to upper motor neuron disease. Because LACV in the cerebrospinal fluid (CSF) is difficult to isolate by culture and to identify by detection of antigen or nucleic acid, the most typical gold standard for diagnosis is serology. Confirmed cases of LACV infections are required to meet both clinical and laboratory requirements set by the CDC's case definition for arboviral disease.²¹ A confirmed neuroinvasive case must meet all the following criteria:

1. Meningitis, encephalitis, acute flaccid paralysis, or other acute signs of central or peripheral neurologic dysfunction, as documented by a physician, *and*
2. Absence of a more likely clinical explanation. Other clinically compatible symptoms of arbovirus diseases include headache, myalgia, rash, arthralgia, vertigo, vomiting, paresis, and/or nuchal rigidity, *and*
3. Isolation of virus from or demonstration of specific viral antigen or nucleic acid in tissue, blood, CSF, or other body fluid; *or* fourfold or greater change in virus-specific quantitative antibody titers in paired sera; *or* virus-specific immunoglobulin M (IgM) antibodies in serum with confirmatory virus-specific neutralizing antibodies in the same or a later specimen; *or* virus-specific IgM antibodies in CSF and a negative result for other IgM antibodies in CSF for arboviruses endemic to the region where exposure occurred.²¹

A probable case is one that meets the clinical definition for neuroinvasive disease and has LACV-specific IgM antibodies in the CSF or serum but lacks convalescent titers, neutralization titers, or testing to help exclude other endemic arboviruses. The clinical case definition for nonneuroinvasive disease requires fever (chills) as reported by the patient or health care provider, as well as the absence of neuroinvasive disease and any more likely clinical explanation; the laboratory criteria are the same as for neuroinvasive disease, excluding those criteria involving the CSF or other CNS fluids or tissues. A change in the 2014 and 2015 clinical case definitions for arboviral disease from the 2011 clinical case definition is that documented fever is not required, whether for neuroinvasive or nonneuroinvasive disease, and fever is not required at all for neuroinvasive disease (reported fever or chills required for nonneuroinvasive disease).²¹ It has been appreciated for some time that the absence of documented fever does not exclude LACV-associated clinical disease, and now this is formally recognized in the epidemiologic definitions of disease.

Active surveillance efforts can increase case findings markedly, as seen in West Virginia,⁸⁵ where after a child died of LACVE in 1987, more than 150 cases were diagnosed during the next 8 years (vs. only 15 cases ever previously reported in West Virginia).¹⁰³ The CDC records from 1987 to 1997 reveal that West Virginia became the most highly endemic state in the United States.²⁵ This trend has continued, with West Virginia highest among the states with 235 (26%) of the 895 suspected or confirmed cases of neuroinvasive California serogroup-associated neuroinvasive disease from 1999 to 2007 (see Fig. 190.1 for relative case rates by county and Fig. 190.2 for total cases of neuroinvasive disease by state, 2004–13).¹²⁴ Knowledge of the public health importance of LACVE is not complete because the virus is distributed discontinuously in the eastern part of the United States, where the disease could be endemic but underrecognized. Nevertheless, more recent use of spatial mapping techniques has increased the understanding of regional transmission patterns.^{12,64,76,124,153} In addition, the high ratio of inapparent to apparent infections (see Clinical Manifestations) implies that most persons who are infected will not come to medical attention, and thus the infection will not be reported.⁸² Even the presentation of symptomatic patients occurs along a continuum from fever and headache to alteration of consciousness and seizures. To improve case diagnosis and reporting to state health departments, clinicians need to cultivate an appreciation for the epidemiology of LACV, the range of clinical presentations of LACVE, and the appropriate diagnostic tests. The virus typically is not recoverable on culture of CSF and therefore requires specific serologic testing (see Laboratory and Radiologic Diagnosis).

Seroprevalence rises with age in endemic areas.^{135,136} Serosurveys have shown that point prevalence rates vary in endemic locations from 30% in rural areas to 15% in urban locations.¹⁰⁹ Although risk appears to be highest in rural areas, many cases occur in suburban residential locations. Some patients with clinical disease have reported travel to

forested recreational areas in endemic regions.^{38,76,142} A case-control study performed in a highly endemic county found several characteristics of the peridomestic environment to be associated with a risk of acquiring LACVE: tree holes on the residential premise, proximity of the house to the forest edge, and the presence of artificial containers and large numbers of discarded tires.¹⁵³ A case-control study in eastern Tennessee also showed an association of LACVE with proximity (within 100 m) of tree holes to the residence, increased time that patients spent outdoors, and increased burden of *A. albopictus* in the peridomestic environment.⁴⁷ A more recent noncontrolled study in West Virginia that investigated the residences of patients with LACVE found the presence of a wooded area in 92.0% and outside containers in 70.5%.⁶⁵ The presence of standing water was observed at almost one-half of the case residences (49.4%), and most case residences (76.7%) were located within 45.6 m (149.0 feet) of a wooded area. In general, these epidemiologic data support the use of public health and spatial mapping techniques to identify hyperendemic areas where preventive efforts should be focused. National and state maps (including county-level data) from the United States Geological Survey (USGS) from 2004 to the present can be found at <http://diseasemaps.usgs.gov/mapviewer/>.

With regard to California serogroup viruses in the United States other than LACV, JCV seroprevalence rates of 5% to 40% have been found in the upper Midwest. In 2014, there were 11 cases of JCV disease reported from 4 states (Massachusetts, Minnesota, Tennessee, and Wisconsin), including the first case reported from Tennessee.⁹⁵ Dates of illness onset occurred from May to September, and the age distribution of patients was bimodal, with four patients younger than 18 years old and six older than 60 years. Seven patients were hospitalized, and none died. Six of the 11 patients were female. In contrast, most of the previously reported cases (21 of 29 in one series) occurred in male patients.¹³³ In contrast to LACV, JCV infections occur earlier, in May or June, and continue through the end of the summer. In addition, JCV is more likely to cause illness in adults than in children.^{38,65} As for SSHV, human infections have been documented by serosurveys in Alaska and throughout Canada.⁵⁹ In these serosurveys, antibody prevalence rates were more than 30% in some areas; seroprevalence in the male population was twice the rate in the female population. Sporadic infection with California serogroup viruses other than LACV is likely to occur frequently in the western part of the United States.¹²² However, symptomatic cases of infection with CEV occur rarely.⁴⁴

PATHOGENESIS

LACV, which infects the salivary glands of the mosquito vector, is introduced into the host's skin and subcutaneous tissue during feeding. Probing alone is sufficient for infection. Completion of a blood meal is not necessary for transmission to occur. Local viral replication in adjacent muscle tissue leads to systemic viremia that seeds the reticuloendothelial system, muscle, and chondrocytes. This seeding results in further amplification of viremia and allows infection of vascular endothelial cells abutting the CNS.^{54,55,77,79} Entrance into the CNS probably is initiated by infection of these vascular endothelial cells, which provide a route for infection of neurons and glial cells.^{77,79} In a murine model, LACV probably gained direct access to the CNS through the bloodstream or olfactory neurons, or both.¹³ The ability to infect mice efficiently by the intranasal route raises the possibility that LACV could use this route to infect its natural hosts. Case reports suggest that vascular involvement in human LACVE may be important in the pathogenesis of focal deficits (from stroke) and more generalized cerebral edema (possibly from vasogenic edema).^{94,104} Polymerase chain reaction (PCR) studies of the location of LACV within the CNS found viral RNA within the cortex but not in other CNS tissues.²⁹ This finding is consistent with the results of magnetic resonance imaging (MRI) in one study that showed evidence of lesions predominantly in cortical areas.¹⁰¹

Most studies indicate that the extraneural phases of viral replication and neuroinvasiveness are mediated largely by the M segment of the genome, primarily through Gc glycoprotein, which appears to promote binding to and entry into cells.^{53,54,55,120,128} A study in adult mice indicated that once the virus has gained access to the CNS, replication in CNS tissue (i.e., neurovirulence) is mediated largely by the L RNA segment,

probably through the viral polymerase.^{46,55} Previous work implicated the M segment in neurovirulence, but in that study neurovirulence was defined as time to death after intracutaneous inoculation.¹²⁸ The host immune response involves neutralizing antibody, which mediates viral aggregation, inhibition of viral attachment to cells, and inhibition of viral penetration and uncoating.⁸⁷ Other aspects of the immune response shown to play a role in protection against LACV infection of the CNS in animal models include CD4⁺ T cells and MxA protein, which is induced by the interferon- α/γ system.^{70,90,123,127} Susceptibility to and complications of LACVE may have an immunogenic component, as indicated by an association of illness and seizures with certain human leukocyte antigens.²² Neuronal cell death may be mediated largely by apoptosis (programmed cell death), as determined by studies in mice,¹¹⁷ and the nonstructural protein NSs has been found to promote apoptosis and to interrupt the RNAi pathway.^{15,131} It is interesting that bc1-2 expression can inhibit apoptosis in certain cell lines.¹¹⁷

CLINICAL MANIFESTATIONS

The clinical spectrum of illness in LACV infections ranges from inapparent infection or mild febrile illness to aseptic meningitis and fatal encephalitis.^{5,6,30,31,33,62,71,101,137,155} The ratio of inapparent to clinically apparent infection ranges from 26:1 to 322:1.⁸⁴ Most clinically apparent infections in children are associated with signs and symptoms of meningoencephalitis and occur within an average incubation period of 5 to 15 days after inoculation. Severe cases tend to mimic herpes simplex virus encephalitis (HSVE) at initial evaluation, whereas mild cases may manifest similarly to enterovirus-associated aseptic meningitis. Of the 665 cases reported from 2004 to 2012, 521 (78%) were classified as encephalitis, 134 (20%) as meningitis, and 10 (2%) as acute flaccid paralysis (see case definition in [Epidemiology](#)). All the patients with acute flaccid paralysis also had meningitis or encephalitis. Nine patients (1%) died. Of the patients with the 562 cases with available data, 543 (97%) were hospitalized.⁴⁹ In largest series of hospitalized children published in 2001, three children had the nearly lethal complication of cerebral herniation.¹¹⁵ In addition, nearly one-half of all patients required admission to intensive care, and one-fourth required mechanical ventilation.^{64,101,124,137}

Children typically have a 3- to 4-day prodrome of fever, headache, and vomiting; diarrhea is usually absent. The illness often progresses such that disorientation (42%) or seizures (46%) may be seen on the day of admission. Most seizures are partial or partial with secondary generalization (58%), and the remaining seizures are generalized. Status epilepticus develops in approximately one-fourth of children with seizures. Rarely, patients may have sudden onset of seizures with little or no preceding fever or headache.¹⁰¹ In a more recent retrospective analysis of 47 patients younger than 18 years of age with LACV infection in western North Carolina, admission signs and symptoms included fever (43%), headache (94%), vomiting (78%), altered mental status (58%), seizures (61%), and hyponatremia (15%).¹⁰⁶ Three more patients (6%) developed hyponatremia during their hospital stay. A case series of LACVE in 10 adults ranging from 20 to 80 years of age found that fever, headache, and hyponatremia were common, as they are for children. Mental status changes occurred in about one-half of adults, but seizures may occur less frequently in adults (20%) than in children.¹⁴⁰ Neuroinvasive disease in adults is probably underrecognized and is not trivial in terms of morbidity, with prolonged acute hospital stays (average stay longer than 1 week) and nearly one-half of patients requiring discharge to rehabilitation facilities. Symptoms or diagnosis of LACV-associated disease in adults may be a sentinel to cases in children and vice versa.

On examination, signs of meningeal irritation and changes in mental status are found in approximately one-fifth to one-fourth and one- to two-thirds of patients, respectively.^{101,106} Focal neurologic signs, principally focal seizures, paresis, aphasia, and abnormal reflexes, are seen in 16% to 25% of patients with LACVE. Focal and generalized seizures occur in 42% to 62% of cases, and status epilepticus develops in 10% to 15%.^{30,100,101,151} Focal neurologic signs, whether found on physical examination, electroencephalographic (EEG) examination, or imaging studies, should be taken as evidence of presumptive HSVE, thus indicating the need to start empiric acyclovir until diagnostic studies have been

completed.¹⁵⁴ Table 190.1 summarizes the clinical characteristics and demographic data of a large series of hospitalized children with LACVE.¹⁰¹

From the same study, the hospital course was complicated by the following: hyponatremia (21%), a finding generally consistent with the syndrome of inappropriate antidiuretic hormone secretion; recurrent or de novo seizures (13%); signs of increased intracranial pressure (ICP; 13%); and, rarely, cerebral herniation (2.3%).¹¹⁵ Approximately one in 10 patients (including the three with herniation and 10 others with recurrent seizures, coma, or both) experienced neurologic deterioration after hospital admission, usually between 36 and 72 hours after admission. Risk factors associated with deterioration were the presence of disorientation or vomiting at admission and a trend toward seizures at admission. Neurologic deterioration appeared to be related temporally to a decrease in serum sodium concentration or an increase in body temperature, findings suggesting that these conditions may also be risk factors for in-hospital deterioration. The tendency for one in 10 hospitalized children with LACVE to deteriorate neurologically after admission represents a significant challenge for clinicians (see [Treatment](#)).

Clinical findings in patients infected with other members of the California serogroup viruses deserve brief mention. JCV infections often are associated with prodromal respiratory symptoms in conjunction with aseptic meningitis or clinical encephalitis. Among 39 patients with proven or suspected CNS infection with JCV, 10 had encephalitis, and seven reported upper respiratory symptoms or pneumonia.^{59,133}

The few patients described with SSHV infection have had manifestations ranging from an influenza-like illness to aseptic meningitis or fatal encephalitis. One fatality was reported in a 14-year-old girl who had symptoms and signs that suggested Reye syndrome.⁴² In a 59-year-old man, radiologic and EEG findings showed a temporal lobe focus, which led to performance of a brain biopsy and a clinical and pathologic diagnosis of herpes encephalitis, even though herpes virus was not isolated. Serologic examination later confirmed the diagnosis of SSHV infection. Mild febrile illness attributed to infection with TV has been described in some patients, and CNS infections with TV have been identified in others.¹⁰⁹ Three cases of symptomatic infection caused by CEV have been reported. All three patients had signs and symptoms of encephalitis.⁶⁶

LABORATORY AND RADIOLOGIC DIAGNOSIS

Despite the lack of an effective antiviral agent for the treatment of LACV, early diagnosis of LACVE is important in guiding triage and management decisions. Initially, such a diagnosis is often probable or presumptive rather than definitive because at best a single elevated IgM or IgG antibody titer is available in the acute phase of illness, meaning that clinicians should continue to be vigilant for alternative diagnoses. In addition, when choosing diagnostic tests for encephalitis, clinicians should communicate with virology laboratory colleagues so that the limitations of these tests are understood. For example, results of viral culture of CSF is usually negative. There have been only two reports of successful growth of LACV from CSF.⁹⁸ Isolation from brain tissue has occurred on four occasions.^{83,102} Improvements in the detection of LACV RNA,^{28,72,92} including nucleic acid–based amplification and reverse transcription PCR, have been tested in mosquitoes and human brain tissue,⁹³ but clinical diagnostic capabilities with blood or CSF samples remain experimental. Therefore, at this time, serologic methods to detect LACV antibody continue to be the best method for diagnosis, with a fourfold rise between acute and convalescent titers remaining the gold standard. IgM-specific antibody to LACV can be detected reliably in serum and CSF by two methods: (1) indirect immunofluorescent antibody (IFA), which is a Food and Drug Administration (FDA)–approved test with rapid turnaround available for use by clinical laboratories; and (2) enzyme immunoassay (EIA), which is available only through the CDC and some state laboratories. The IFA assay is a two-stage “sandwich” procedure. In the first stage, the patient’s serum is diluted, added to appropriate slide wells bearing the antigen, and incubated. After incubation, unbound antibodies are washed away, and then each antigen well is overlaid with fluorescein-labeled antihuman goat antibody to IgG or IgM. The slide is incubated a second time, to allow complexes of antigen and either LACV IgM or LACV IgG antibody to react with the

FIG. 190.5 California serogroup viruses immunofluorescent antibody. The indirect immunofluorescent antibody assay is a two-stage “sandwich” procedure. In the first stage, the patient’s serum is diluted, added to appropriate slide wells bearing the La Crosse virus antigen, and incubated. After incubation, unbound antibodies are washed away, and then each antigen well is overlaid with fluorescein-labeled antibody to immunoglobulin G (IgG). The slide is incubated a second time, to allow complexes of antigen and antibody to react with the fluorescein-labeled anti-IgG. After the slide is washed, dried, and mounted, it is examined by fluorescence microscopy. Positive reactions appear as cells exhibiting bright apple-green cytoplasmic fluorescence against a background of red negative control cells. The so-called starry night pattern of stippling along the cell membrane and cytoplasm is a finding unique to the California serogroup viruses. Semiquantitative end-point titers are obtained by testing serial dilutions of positive specimens.^{3,18}

fluorescein-labeled anti-IgG. After the slide is washed, dried, and mounted, it is examined by fluorescence microscopy. Positive reactions appear as cells exhibiting bright apple-green cytoplasmic fluorescence against a background of red negative control cells ([Fig. 190.5](#)). The cutoff for a positive IgM or IgG IFA is a titer of 1:16 or higher. One study used the standard fourfold rise in antibody titer as the gold standard for comparison to diagnosis by single acute-phase LACV titers and reported that a single elevated acute LACV IgM or LACV IgG titer by IFA has a sensitivity of 75% and a specificity of 98%.¹¹¹ The available IFA kit also provides tests for St. Louis encephalitis virus (SLEV), eastern equine encephalitis virus (EEEV), and western equine encephalitis virus (WEEV).³ The IFA test for LACV IgM has the advantage of providing a rapid diagnosis within 24 to 48 hours, but a single titer defines only a probable case under the CDC case definition. For a probable case to become a confirmed case, it is necessary to obtain positive serum convalescent titers by either IFA or EIA (i.e., a fourfold rise) or confirmatory neutralization titers performed at the CDC, done either on a serum sample (acute or convalescent) or CSF (see [Epidemiology](#)).

IgM capture EIA is used by the CDC as a sensitive serologic test that detects virus-specific IgM in 83% to 100% of cases (see [Fig. 190.5](#)).^{3,10,11,18,19,41,43} An IgG capture EIA method has been developed as well, but preliminary work suggests that it lacks reliability at this time.^{80,97} The main advantage of IgM capture is that it is less operator dependent than the IFA method, which requires careful observance of visual reading criteria by experienced personnel. For this reason, IgM capture EIA is the method used by the CDC for detection of LACV IgM. Sometime in the future, the CDC may replace the EIA capture method with a microsphere immunofluorescence assay (MIA) for the concurrent detection of either IgM or IgG antibody to LACV, WNV, SLEV, WEEV, EEEV, and Powassan virus (a tick-transmitted flavivirus) (A.J. Basile, personal communication). An MIA is similar to an EIA, except that viral antigens are either directly attached to beads instead of a plate or attached indirectly by an intermediate antibody. Results are read by use of a modified flow cytometer. Relative advantages of the MIA in comparison with EIA include decreased time to test

completion, improved technical ease, and decreased sample volume. Confirmatory testing of patients with a positive IgM result by IFA or EIA involves the detection of LACV-specific neutralizing antibodies by plaque reduction assay, performed by the CDC. Despite the current CDC recommendations that a probable case should be confirmed with additional testing, more recent work suggests that a single acute serologic sample tested by IFA may eventually be considered sufficient for clinical purposes if not also epidemiologic uses.¹¹¹ For more on surveillance and reporting of cases, see also the CDC case definition of arboviral disease in the [Epidemiology](#) section. Instructions for sending diagnostic specimens to the CDC Division of Vector-Borne Diseases Arbovirus Diagnostic Laboratory can be found at <http://www.cdc.gov/nceid/dvbd/specimensub/index.html>. In fatal cases, nucleic acid amplification, histopathologic examination with immunohistochemistry, and virus culture of autopsy tissues can also be useful. Only a few state laboratories or other specialized laboratories, including those at CDC, are capable of doing this specialized testing.

In all diagnostic tests for LACVE, even a minimal decrease in specificity (a false-positive result) can present a key clinical dilemma, with the potential to distract clinicians from diagnosis of treatable conditions. Unfortunately, neither currently available serologic method for LACV IgM detection can guarantee 100% specificity, especially because in rare instances LACV IgM reportedly has remained elevated in serum for more than 1 year. Therefore, even in the context of positive acute titers for LACV, it may be prudent to consider continuation of empiric therapy for HSVE with intravenous acyclovir until a negative CSF PCR assay result for herpes simplex virus is obtained. Although the occurrence of false-positive test results for LACV is the major concern clinically, false-negative results may occur as well, particularly within the context of a rapidly progressive acute infection. IgM antibodies are generally first detectable at 3 to 8 days after onset of illness and usually persist for 30 to 90 days. Serum collected within 8 days of illness onset may not have detectable IgM.²¹ In patients with a negative result for IgM and a clinical syndrome compatible with LACVE, it may be helpful to obtain convalescent-phase IgM and IgG titers in 1 to 2 weeks and in some cases in as little as 3 or 4 days from initial testing at clinical presentation.

Ancillary laboratory examinations for LACV infection were well outlined in one series (Table 190.2).¹⁰¹ The total CSF leukocyte count was elevated only moderately (the median white blood cell [WBC] count in the CSF was 75 cells/mm³), with a predominance of lymphocytes, and 25% of patients had sparsely elevated red blood cells in the CSF.¹⁰¹ In a more recent retrospective analysis of 47 patients with probable or confirmed LACVE, the median CSF WBC count was 160/mm³ (range, 10–1063/mm³), with a median lymphocyte percentage of 44% (0–98%).¹⁵¹ In the classic study, the 75th percentile for the CSF protein level was 45 mg/dL (normal range, 5–40 mg/dL), consistent with numerous reports in which elevated protein levels were observed in less than one-third of cases.^{5,30,33,71,101} Approximately 10% of children had negative or

equivocal findings on initial CSF analysis, only to have numerous WBCs in the CSF within 24 to 48 hours on repeated lumbar puncture. The peripheral WBC count was elevated ($\geq 15,000$ WBCs/mm³) in half of the cases at admission and was frequently associated with neutrophilia, which in general may raise suspicion for bacterial meningitis or partially treated bacterial meningitis. Serum electrolyte values should be monitored for hyponatremia, which occurs frequently and has been associated with worsening clinical status in LACVE.¹⁰¹

Even though the Infectious Diseases Society of America recommends that all children and adolescents with encephalitis should have brain MRI with and without contrast enhancement, optimally with diffusion-weighted imaging, at this time most available data in children with LACVE are from computed tomography (CT) scans (see [Treatment](#) for basic recommendations on obtaining imaging in this clinical setting).¹⁴⁶ In 127 hospitalized children with LACVE, 92 had non-contrast-enhanced CT scans. Only 11 of these scans had abnormal findings; eight showed generalized edema, and three showed focal findings, all in supratentorial locations.¹¹⁵ In three children whose courses were complicated by cerebral herniation, CT scans detected an abnormality only after the herniation event (i.e., CT scans on admission were normal). From this same series, each of 10 children had MRI of the brain; four of these children had abnormal MRI findings that showed focal areas of gadolinium enhancement, predominantly in cortical areas (Fig. 190.6).¹⁰¹ Case reports of LACVE suggest that MRI may reveal lesions not detected by CT. In a 20-month-old infant with right hemiparesis, CT findings on admission were normal, but MRI on day 1 showed evidence of acute infarction of the left basal ganglia.⁹⁴ In a 12-month-old child with clinical evidence of worsening neurologic status, MRI showed areas of increased signal intensity in the periventricular white matter, even though the initial CT scan had been normal.⁵⁰

EEG abnormalities have been found in 71% to 90% of patients tested. Focal EEG findings, usually slowing, may appear in as many as 44% of abnormal EEG tracings.^{30,100,101} Periodic lateralizing epileptiform discharges (PLEDs), previously thought to be virtually pathognomonic for HSVE, also occur in LACVE. In a case series of LACVE, 8 of 90 EEG tracings were positive for PLEDs^{39,101}; in four of these eight cases, patients required continuous EEG surveillance to monitor treatment of nonconvulsive status epilepticus.¹⁰¹ Patients with PLEDs represent a worrisome subgroup of all patients with LACVE because they have longer, more complicated hospitalizations and are likely to have worse long-term outcomes.⁴⁰

DIFFERENTIAL DIAGNOSIS

The principal consideration in the differential diagnosis of LACVE is HSVE.^{101,130} Clinical descriptions of LACVE consistently disclose a high rate of focal neurologic findings or focal seizures, or both (~30%). The frontal and temporal lobe locations of abnormalities detected by EEG examinations (including PLEDs) and by brain imaging studies in some

TABLE 190.2 Laboratory Values at Admission in Patients With La Crosse Encephalitis

Variable	Mean Value ± SD	Range	PERCENTILE					Remarks
			10th	25th	50th	75th	90th	
Cerebrospinal Fluid								
White blood cell count (per mm ³)	130 ± 151	2–867	10	26	75	184	316	<200/mm ³ in most cases
Differential count (% lymphocytes)	—	2–100	10	27	62	77	90	Predominance of lymphocytes
Red blood cell count (per mm ³)	71 ± 213	0–1,500	0	1	5	20	177	Elevated (≥20/mm ³) in 25%
Glucose (mg/dL) a	75 ± 20	37–149	56	62	71	83	105	Normal
Protein (mg/dL)	37 ±± 15	10–85	20	27	34	45	56	Rarely elevated
Peripheral Blood								
White blood cell count (per mm ³)	15,700 ± 5,900	6,800–49,700	8,900	11,500	14,800	19,000	22,600	Usually elevated (>15,000/mm ³)
Differential count (% polymorphonuclear leukocytes)	—	17–94	58	66	76	82	86	Predominance of polymorphonuclear leukocytes

Data from McJunkin JE, de los Reyes EC, Irazuzta JE, et al. La Crosse encephalitis in children. *N Engl J Med*. 2001;344:801–807.

FIG. 190.6 Radiographic studies in patients with severe La Crosse encephalitis. (A) Computed tomography (CT) scan (obtained on the second hospital day) of an 8-year-old boy with severe La Crosse encephalitis complicated by uncal herniation reveals brain edema with associated obliteration of perimesencephalic cisterns (arrows). (B) T2-weighted magnetic resonance image obtained in a 7-year-old boy with severe La Crosse encephalitis shows focal areas of increased signal intensity in the right temporoparietal and left frontotemporal regions (arrows). A CT scan obtained at the time of uncal herniation 7 days earlier showed hypodensity in the same areas. (From McJunkin JE, de los Reyes EC, Irazuzta JE, et al. La Crosse encephalitis in children. *N Engl J Med.* 2001;344:801–807.)

cases of LACVE initially may suggest a presumptive diagnosis of HSVE.^{5,101} Hemorrhagic pleocytosis, which can occur in both HSVE and LACVE, also may favor a presumptive diagnosis of and therapy for HSVE. Because delay of therapy for HSVE is associated with a poor outcome, a reasonable approach in cases of encephalitis with focal findings or severe encephalitis is to treat empirically for HSVE with intravenous acyclovir pending definitive diagnosis.^{146,152}

In patients with less fulminant signs of CNS infection, enteroviral aseptic meningitis is a common consideration, especially because it often occurs with similar seasonality, in summer and early fall. The presence of rash, pharyngitis, conjunctivitis, or myocarditis is a clue to enterovirus and is not characteristic of LACV infection. In a study comparing enteroviral CNS infection with LACVE, patients with LACVE were significantly more likely to have aphasia, loss of consciousness, seizure, and admission to the pediatric intensive care unit than were patients with enteroviral CNS infection.⁶⁸

For undervaccinated or unvaccinated persons and communities, poliomyelitis remains an important diagnostic consideration. In September 2005, a 7-month-old Amish child from Minnesota with failure to thrive, diarrhea, and recurrent infections was diagnosed with type 1 vaccine-derived poliovirus (VDPV) in the context of newly diagnosed severe combined immunodeficiency.²⁴ Although 8 of 23 children (including the infant) in the index community tested positive for VDPV, none had paralytic disease.¹ Mumps encephalitis is another consideration, even in the absence of parotid swelling, and low or low-normal CSF glucose levels may be a clue to this diagnosis.⁹³

Patients with Rocky Mountain spotted fever may exhibit signs of CNS disturbance, and one should remember that rash may be absent in 20% of patients. *Bartonella henselae* infection (cat-scratch disease) or *Mycoplasma pneumoniae*-associated encephalopathy may be valid considerations in the differential diagnosis. Certainly, other Arboviridae should be considered, and many laboratories now test simultaneously for Arboviridae known to occur in the United States (WNV, SLEV, EEEV, and WEEV) in patients with severe seasonal (summer or fall) encephalitis. A rare and tragic consideration in a child presenting with encephalitis is rabies, which may occur in the absence of a known

animal bite. Certainly, a wide array of viruses, bacteria, and even amebas and parasites can cause CNS disease. These etiologic agents are reviewed in other chapters of this text as well as in the Infectious Diseases Society of America practice guidelines for the management of encephalitis.¹⁴⁶

TREATMENT

Because no specific FDA-approved antiviral treatment of LACVE is currently available, careful supportive care is the mainstay of therapy. A reasonable general supportive strategy is to assess these patients as one would assess children with closed head injury. In both instances, (1) changes in the level of consciousness cannot be assumed to be caused by a normal need to sleep and therefore require serial monitoring, and (2) changes in the level of consciousness generally are the best and earliest indicators of evolving intracranial disease, as opposed to later brainstem signs such as pupillary abnormalities or bradycardia with hypertension. Therefore, serial monitoring of the level of consciousness is the most important aspect of neurologic monitoring (i.e., use of the Glasgow Coma Scale [GCS]), even if the child has minimal changes in level of consciousness at the time of admission.

Three particularly important decision points in management depend on the presence or absence of (1) disorientation, (2) further deterioration in GCS scores, and (3) focal findings. Once the child becomes disoriented (GCS score typically <13), as shown by changes in mental status in an older child or perhaps by lack of recognition of parents in an infant, the child is monitored best in an intensive care setting. Children presenting with seizures on admission or children documented to have elevated opening pressure on lumbar puncture also deserve consideration for admission to intensive care, as do those with unremitting vomiting or headache or both despite appropriate medical care on the general pediatric ward.¹⁰¹ Further deterioration in the GCS score to 8 or lower generally indicates that the patient no longer is able to protect the airway adequately, and appropriate intervention is needed. Cases suggesting HSVE because of focal findings or coma or both warrant presumptive treatment with intravenous acyclovir pending definitive diagnosis.

Many of the same strategies that apply in treating children at risk for increased ICP are used in treating children with LACVE. A reasonable approach is to perform funduscopy and to consider a non-contrast CT scan of the brain to evaluate for a mass lesion or other cause of increased ICP that would be a contraindication to lumbar puncture. When performing lumbar puncture, measure the opening pressure whenever possible. In patients with encephalitis, brain MRI with and without gadolinium contrast and with diffusion-weighted imaging is the recommended imaging modality, and this should be performed as soon as feasible. Nevertheless, practical considerations (e.g., the need to perform lumbar puncture with minimal delay and the lack of the patient's cooperation because of young age or disorientation) still often favor CT over MRI in the early phase of illness. General treatment strategies in patients at risk for increased ICP include the following: airway and (if necessary) ventilatory management designed to avoid hypercapnia; hemodynamic management to optimize mean arterial pressure (and presumably cerebral perfusion pressure); neurologic strategies to optimize control of seizures; and strategies designed to avoid hyposmolality, hyperthermia, and other factors that may exacerbate intracranial hypertension or avoidable increases in the cerebral metabolic rate. Intubated patients should be sedated adequately and may need additional analgesia or sedation before noxious procedures such as endotracheal suctioning are performed.

In a large series of hospitalized patients with LACVE, the condition of 1 in 10 patients with LACVE deteriorated neurologically after admission. Risk factors identified to occur more often before in-hospital deterioration were the occurrence of disorientation (consistent with a GCS score ≤ 13), vomiting, and seizures.¹⁰¹ In addition, hyponatremia and hyperthermia may be related temporally to clinical deterioration in patients with LACVE.¹⁰¹ Regarding therapeutic implications of the risk for development of hyponatremia, isotonic fluids (normal saline or 5% dextrose in normal saline) should be used at maintenance rates, in addition to deficit replacement, to minimize the tendency for the development of hyponatremia while maintaining intravascular volume.¹⁰¹ Serum sodium concentration should be monitored approximately every 8 hours during the acute phase of the illness. If evidence of the syndrome of inappropriate antidiuretic hormone secretion is documented and cerebral salt wasting is ruled out by careful monitoring of fluid status as well as sodium level and osmolality of the urine and serum, careful restriction of fluids may be considered. Because hyperthermia may be associated with neurologic deterioration in some patients, a low threshold for prevention or treatment of fever with antipyretics is recommended. In critically ill patients with evidence of increased ICP, methods other than antipyretics (e.g., cooling blankets) may be considered to address persistent hyperthermia, provided shivering and discomfort are controlled.

Patients with neurologic deterioration may need to have repeated EEG or brain imaging studies or both because nonconvulsive status epilepticus can occur and because the initial brain imaging results may be normal, but later imaging may show evidence of cerebral edema. Some experience has been gained in the monitoring of ICP in LACVE.⁸³ In one particular study, high ICP was documented in three of six patients in whom monitors were placed, and such monitoring was considered by clinicians to be a useful adjunct in these cases.¹⁰¹ Establishment of clinical and imaging criteria to determine which patients could benefit from insertion of an ICP monitoring device remains a dilemma, particularly because ictal and postictal events in LACVE can confound the neurologic examination regarding possible signs of increased ICP.

No specific antiviral therapy is approved by the FDA for the treatment of LACV infection or LACVE. Although previous laboratory studies suggested the potential of ribavirin (RBV) as a therapeutic agent,^{23,32,73,74,104,119,129,134} a report summarizing the largest study of antiviral treatment of LACVE documented overall poor clinical efficacy and a narrow therapeutic index.¹⁰⁵ This report summarized three studies of children treated with intravenous RBV during a 10-year period from 1994 to 2003, each study exploring a different phase (I, IIA, and IIB) of clinical trial development. In a group of 15 children treated in phase I and phase IIA, RBV appeared safe at moderate dosing, but on the basis of steady-state RBV levels of 9.3 μM , estimated CSF levels were less than 20% of the half-maximal effective concentration of RBV for LACV. No trends to suggest efficacy of intravenous RBV could be detected

in the statistically underpowered phase IIA randomized controlled trial. At the escalated dose used in phase IIB, each of the first two enrollees experienced adverse effects (elevated serum ammonia and elevated serum pancreatic enzymes, respectively) considered likely to be related to RBV, and therefore the trial was discontinued. In view of the limitations of RBV for LACVE, it is encouraging to note a group of novel broad-spectrum RNA virus inhibitors known as the pyrazinecarboxamide derivatives: T-705 (favipiravir), T-1105, and T-1106.⁴⁸ These compounds have demonstrated good activity in treating laboratory animals with viral infections caused by various RNA viruses, including influenza virus, arenaviruses, bunyaviruses, and others. Whether these agents will prove capable of treating viral infection in the CNS, however, remains to be investigated. Most recently, research on inhibition of certain cellular enzymes called deubiquitinases, important for cellular processes such as the response to unfolded proteins in the endoplasmic reticulum, implicates this pathway as a possible target for the inhibition of replication of certain RNA viruses, including LACV.¹¹⁸ Even though this finding is certainly interesting, the mechanism of inhibition of viral replication has not been elucidated. In summary, the search for antiviral treatment of LACVE remains important because of the high morbidity caused by this virus as well as its potential to increase in prevalence and severity.^{51,101}

OUTCOME

LACV infections are associated with a case-fatality rate of up to 1.9%.⁶⁴ A series of hospitalized patients ($n = 127$) showed nearly lethal disease from cerebral herniation in three cases. Furthermore, in this study many patients required mechanical ventilation (25%) or intensive care (50%).¹⁰¹

In the 1960s and 1970s, psychometric evaluation of patients who had recovered from their acute LACV-associated encephalitis failed to show significant differences in standard tests of cognitive ability compared with control subjects or normative data in the general population.^{100,125} In 2001, however, a study of 28 recovered patients, most of whom had severe LACVE (e.g., associated with seizures or coma, including three patients with cerebral herniation), showed a mean full-scale intelligence quotient (IQ) of 87.8 (95% confidence interval, 82.2–93.2). Thirty-five percent of these patients had an IQ lower than 80, and 46% demonstrated significant disparities between verbal and performance IQ scores. In addition, 60% of this group had test results indicative of attention deficit–hyperactivity disorder.¹⁰¹ This study lacked a contemporaneous, matched control group, but certainly compared with normative data, these findings strongly suggest that neurocognitive and behavioral deficits do occur after LACVE, particularly in patients with severe disease. In addition, previous data indicating changes in performance on tests administered before and after illness suggested effects in children who were more seriously ill.¹⁰⁰ In another small series, visual-motor function abnormalities and intellectual impairment were observed more often in patients who had focal abnormalities during the acute illness.¹⁰⁰

Of the patients who recover from LACVE, 6% to 15% have recurrent seizures.^{30,36} The risk of having a recurrent convulsive disorder is approximately 25% in patients who experienced a seizure during the acute phase of illness.^{36,56} The interval between the onset of recurrent seizures and recovery from acute infection ranges from a few days to years (mean, 4 years).³⁶ Persistent hemiparesis was a residual abnormality in two of 151 patients monitored for up to 6 years after recovery from LACVE, but one patient had a brain biopsy performed, which may have accounted for some of his neurologic deficit.³⁰ Unilateral infarction of the basal ganglia and hemiparesis were described in the case of an infant.⁹⁴ Another infant with a presumed LACV infection initially had an apparent neurodegenerative disease secondary to acute disseminated encephalomyelitis.⁵⁰ See the description at the beginning of this chapter for a discussion of the economic costs of LACVE.

PATHOLOGY

The original model of LACV disease in LACVE proposed that the virus first replicates in muscle cells, thus leading to viremia with subsequent hematogenous spread to the vascular endothelium and ultimately to access in the CNS.^{13,78} In a more recent study, weanling mice inoculated

intraperitoneally with 100 median lethal doses of LACV/human/1960 had histopathologic lesions on day 6 after inoculation in the following: (1) the brain, including olfactory bulb, cerebral cortex, thalamus, hippocampus, and medulla oblongata; and (2) the spinal cord, including perivascular cuffing, neuronal degeneration, necrosis (either single cell or small foci), and apoptosis.¹³ Histopathologic changes were minimal outside the CNS. Viral antigens were not observed in the nasal turbinates, muscle, spleen, or pancreas. However, viral antigen was detected in the olfactory bulb of the brain, thalamus, cerebrum, medulla oblongata, and spinal cord. Therefore this more recent study suggests that LACV can enter the CNS through the olfactory neurons from nasal olfactory epithelium, although the virus may alternatively or additionally enter through the bloodstream and vascular endothelium.

Pathologic descriptions of two fatal cases in humans have been reported.⁸³ In gross appearance, the brain was swollen, and the meninges were congested. The principal brain lesions were neuronal degeneration, patchy inflammatory lesions, and vasculitis. The cerebrum and basal ganglia were the principal sites of involvement, but petechial hemorrhages and edema were noted in the spinal cord of one patient. In both cases, lesions in the cerebrum were confined to the frontal, parietal, and temporal lobes, and the cerebellum was not involved. Focal inflammatory lesions and perivascular reactions were composed primarily of mononuclear cells. Neuronolysis and neuronophagia were observed in foci of inflammation and necrosis, along with reactive polymorphonuclear, mononuclear, and microglial responses. Small extravasations of erythrocytes were seen, as were lymphocytic perivascular cuffs, but inclusion bodies were not. In one case, a focal area of necrosis, hemorrhage, and formation of a hematoma was present in the temporal lobe, a finding corresponding to a mass lesion seen on CT. From a patient in a separate case report, brain biopsy material examined by indirect immunofluorescence demonstrated LACV antigen in neurons and perhaps in endothelial cells. The same biopsy material from this patient showed minimal necrosis and perivascular cuffing on light microscopy.¹⁰² The finding of minimal necrosis despite abnormal CT findings and deep coma is interesting in view of the relatively benign outcome of LACVE in most patients, even in those who experience deep coma or exhibit CT abnormalities. This finding is in marked contradistinction to HSVE, in which the presence of either coma or CT lesions is a poor prognostic factor, consistent with the extensive necrosis seen on pathologic examination.¹⁵²

PREVENTION

Reduction of exposure to mosquito bites is the best method for prevention of infection by LACV or other mosquito-borne viruses. To accomplish this goal, community campaigns have emphasized using repellent, using barriers (mosquito nets, screens, or protective clothing), avoiding peak biting hours (dawn until dusk), and eliminating mosquito breeding sites. Large-scale spraying of insecticides is not an effective intervention for elimination of *O. triseriatus* because this tree-dwelling mosquito tends to be protected by the leaf canopy of its habitat. Public health prevention has focused on common-sense methods of elimination of breeding sites of *O. triseriatus*. Such efforts in endemic areas have included removal of used tires and other containers that hold small pools of water and (less commonly) sealing of tree holes with cement or gypsum wool insulation.¹⁴² Other methods of minimizing standing water include drilling holes in tire swings so that water drains out; emptying standing water from flower pots, buckets, and barrels; replacing water in bird baths weekly; and emptying children's wading pools and storing the pools on their side after use.⁹³ Home public health or mosquito control program visits to patients with new cases of LACVE may identify risk factors around the home or in neighboring areas, with implications for uninfected siblings of the index case and possibly for other children in the community. Counties identified with cases may be targeted during the subsequent spring for educational town meetings or television coverage or interventions such as tire removal campaigns. Such targeted interventions have been tracked in highly endemic areas of West Virginia in recent years. The proper use of insect repellents and avoidance of tree-shaded areas during the vector's active feeding period (from dawn until dusk) may confer a reduction in risk by minimizing exposure to the vector.

Repellents are synthetic compounds or derivatives of plant oils that can be used during outdoor activities when mosquitoes are present to discourage mosquitoes from biting. The most active insect repellents for use on skin contain either *N,N*-diethyl-*m*-toluamide or *N,N*-diethyl-3-methyl-benzamide (DEET), picaridin (KBR 3023), IR3535 (3-[*N*-butyl-*N*-acetyl]-aminopropionic acid, ethyl ester), or the plant-based oil of lemon eucalyptus and its synthetic equivalent, *p*-menthane-3,8-diol.² Insect repellents acceptable for children may contain up to 30% DEET per recommendation of the American Academy of Pediatrics (and up to 50% DEET per recommendation of the CDC), but DEET-containing products should not be used on infants younger than 2 months. As of 2005, the American Academy of Pediatrics and the CDC revised recommendations such that repellents containing picaridin are considered an acceptable alternative to DEET.² Oil of lemon eucalyptus should not be used in children younger than 3 years, according to specifications of the Environmental Protection Agency. A possible advantage of DEET and permethrin is that each has been proven to repel ticks (and to kill ticks in the case of permethrin). DEET is an effective solvent and should be used with caution next to clothing because it may dissolve some plastics, rayon, spandex, or other synthetic fibers. In contrast, permethrin is a repellent and insecticide registered by the Environmental Protection Agency for use on clothing and will provide excellent protection through multiple washes. It should not be applied to skin. All products should be used as directed by the manufacturer.

The potential for development of a vaccine comes from work with a truncated Gc protein preparation that induces a protective immune response in suckling mice through generation of neutralizing antibodies.¹¹⁶ Protection against neuroinvasion was achieved by interruption of transient viremia, which occurred just after inoculation of the virus. A DNA-based vaccine that encodes viral glycoproteins (Gc and Gn) also induced a protective neutralizing antibody response in mice.^{115,127} Should ecologic preventive measures fail to lower disease rates in endemic areas, development of a vaccine for use in persons living in these areas may prove worthwhile.

Acknowledgments

Regarding the interpretation of diagnostic studies for LACV, the authors recognize the valuable input of Kathy Mack, Supervisor of the Virology and Immunoserology Laboratories at Nationwide Children's Hospital, and Linda Minnich, Virology Supervisor at Charleston Area Medical Center Memorial—Charleston. We also thank Marc Fischer, MD, MPH, medical officer at the CDC Division of Vector-Borne Diseases and liaison to the American Academy of Pediatrics Committee on Infectious Diseases from 2010 to 2012, for his insight into the epidemiologic investigation of arboviruses.

191A ■ Rift Valley Fever

Gail J. Harrison

Rift Valley fever (RVF) is a severe, mosquito-borne disease that is caused by a phlebovirus of the family Bunyaviridae and affects both domestic ruminant animals and humans. Outbreaks usually occur during years of heavy rainfall. RVF is caused by a virus with selective affinity for the parenchymal cells of the liver, which undergo characteristic eosinophilic degeneration. Infection with RVF virus causes a short but severe disease in sheep and cattle and other domestic mammals. Most pregnant ewes and cows abort, and more than 90% of newborn lambs die. Case-fatality rates in older sheep and cattle are lower but nonetheless significant. People usually acquire the infection from direct contact or aerosols generated from the body fluids and tissues of animals dying of the disease and from bites of infected mosquitoes, especially during epidemics.^{7,14,27} In humans, Rift Valley virus causes hepatitis, encephalitis, retinitis, and hemorrhagic fever. The public health importance of this disease in humans is emerging because outbreaks in Africa, sub-Saharan Africa, Madagascar, Saudi Arabia, Yemen, and Egypt have resulted in an increase in human fatalities, including neonatal deaths, along with miscarriages and fetal deaths in pregnant women.^{1,3,5} (Fig. 191A.1). With the presence of the competent mosquito vectors in currently RVF-free countries, the wide range of animal susceptible to infection with RVF virus around the world, global changes in climate and geography, and increased animal trade and human travel, RVF may emerge as a global pathogen in the near future, potentially threatening Europe and the Americas.^{12,26,29} In addition, RVF virus has been classified as a potential bioterrorist agent.^{7,14}

HISTORY

RVF probably has occurred for many years in Africa and was recognized first at the beginning of the 20th century with the introduction of intensive livestock husbandry. In 1912 large numbers of newborn lambs died of an unknown disease in the Rift Valley of Kenya, and in the following year the clinical features were described. Daubney and associates⁹ proved that the causal agent was a filterable virus that they suspected was transmitted by mosquitoes because animals protected by screens did not contract the disease. In 1944 the virus was isolated from mosquitoes caught in the Semliki Forest in western Uganda, and it was proved later that *Erethmapodites chrysogaster* was able to transmit the infection under experimental conditions. Between 1950 and 1974 at least 15 major epizootics of RVF occurred in livestock in various areas of sub-Saharan Africa. During 1975 an extensive epizootic of RVF took place in South Africa, with many human cases and several deaths documented.^{11,12}

An extensive epizootic of RVF also occurred in lower Egypt in 1977. Hundreds of thousands of domestic animals, including cattle, buffaloes, goats, and sheep, were lost. Associated with this epizootic was the largest human epidemic of the disease ever known, in which 200,000 humans were infected and 600 died.¹⁷ This outbreak emphasized the increasing threat of RVF to humans and domestic animals and showed that RVF virus was an important cause of hemorrhagic fever in Africa. In 1987, an epidemic of RVF occurred in Mauritania after flooding of the Senegal River basin following completion of the Diama Dam; at least 1200 human cases and 200 deaths occurred in one affected area alone. Epidemics and epizootics were reported in Madagascar in 1990,¹⁹ in Egypt in 1993,⁴ in eastern Africa in 1997 to 1998,² and in Yemen and Saudi Arabia in 2000. In November 2006 through January 2007 Kenya experienced an outbreak of RVF, with a total of 404 cases, 118 deaths,

and a case-fatality rate of 29%. Similar to previous outbreaks, this more recent outbreak was associated with a heavy rainfall, and most cases occurred in young men, who herded and slaughtered livestock, and in young women, who likely handled uncooked animal products as they prepared meals for the family.⁸ The cases in the Arabian peninsula are the first outside Africa and demonstrate the potential of RVF to spread. Based on isolation of the virus, RVF probably occurs sporadically throughout most of sub-Saharan Africa. Zinga virus, previously described as a cause of sporadic human disease in central Africa, has been shown to be a strain of RVF virus. With increase in international trade and tourist travel, as well as climate changes affecting northern Africa and southern Europe, it is likely that future outbreaks of RVF may soon affect the agricultural industry and humans in Europe, Asia, and the Americas.^{7,22,25,28}

ETIOLOGIC AGENT

RVF virus is a member of the genus *Phlebovirus*, belonging to the *Bunyaviridae* family of viruses. It is a negative-stranded RNA virus, with tripartite S, M, and L segments of its RNA. It is a biosafety level 4 pathogen that is easily cultivated in Vero cells or in mice from blood and tissue specimens of infected animals and human patients. It also is classified as a category A overlap select agent by the Centers for Disease Control and Prevention.⁷ The virus is destroyed by solvents such as ether and is inactivated readily by formalin; it is destroyed by heating at 56°C for 40 minutes. When stored at 4°C or –10°C, the virus loses its infectivity in approximately 3 months. The virus can be preserved indefinitely on dry ice at –70°C or in lyophilized form.

Fully formed virions are spherical and approximately 94 nm in diameter. They mature in the cytoplasm, although intranuclear inclusions occur in vivo and in cell culture. The virus multiplies readily in a variety of cell lines of animal and human origin. The virus is highly pathogenic for mice, young rats, and hamsters, and death occurs in 95% to 100% of these animals 36 to 96 hours after inoculation.

VECTORS AND EPIDEMIOLOGY

In studies in South Africa, the virus has been transmitted experimentally by a variety of mosquitoes, including *Culex theileri*, *Culex zombaensis*, *Culex neavei*, *Aedes juppi*, *Anopheles*, and *Erethmapodites quinquevittatus*. Epizootics of RVF have occurred in years of unusually heavy rains that filled natural depressions in the land (pans or dambos), thereby favoring the proliferation of flood-water mosquitoes. Studies in Kenya have shown that transovarial transmission of the virus in pan-breeding *Aedes* of the subgenus *Neomelanoconion* is the probable mechanism of virus maintenance and periodic recrudescence. Seroprevalence in humans in Kenya ranges from 2% in children to 30% in older men and women, with young men and women with reported seroprevalence of seropositivity of 13% to 18%. Risk factors for seropositivity included contact with dead animals and slaughterhouses.^{22,26} *Culex pipiens* was implicated as a vector in Egypt during the 1977 to 1978 epidemic. During epizootics, domestic livestock serve as viremic, amplifying hosts in the transmission cycle. Although currently the virus is limited to Africa and the Middle East, regions in Europe and North America have mosquito genera capable of transmitting RVF virus. One seroepidemiologic study in Saudi Arabia indicated that 5% of children and adolescents were seropositive for

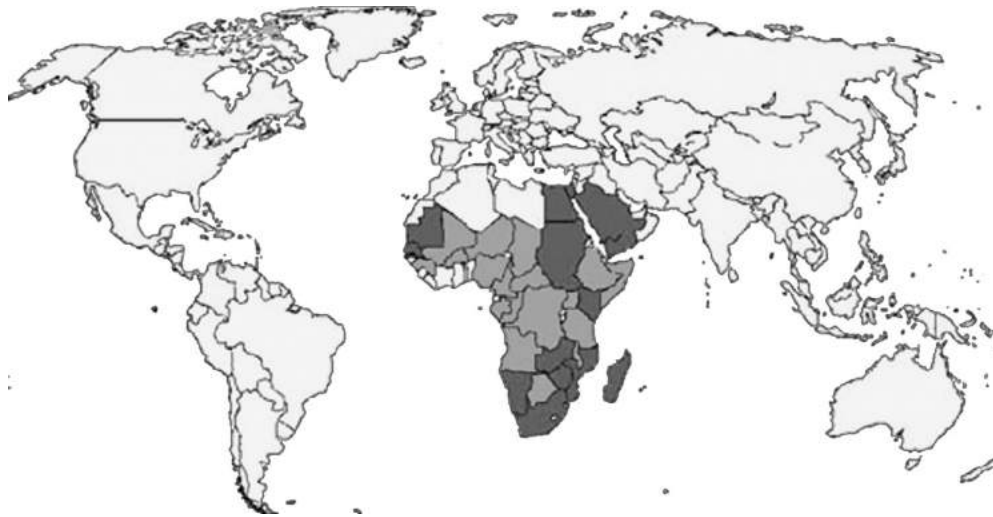

FIG. 191A.1 Rift Valley fever world distribution map. (From Centers for Disease Control and Prevention Special Pathogens Branch. Available at: <http://www.cdc.gov/ncidod/dvrd/spb/mnpages/dispages/rvf/rvfmap.htm>.)

RVF virus.²⁶ Prolonged periods of rainfall, which allow mosquito eggs to hatch, may increase chances for RVF outbreaks, and “early warning systems” using satellite measurements of sea surface temperature, rainfall, and vegetation have been used to predict human and livestock outbreaks of RVF in Africa.^{7,14} In addition to arthropod-borne transmission from domestic livestock to humans by mosquitoes, RVF virus also is transmitted by aerosol and by direct contact with infected tissues from aborted livestock or carcasses of freshly slaughtered animals infected with RVF virus. Therefore persons who herd, care for, or slaughter livestock, as well as persons who prepare raw meats for cooking and consumption, are at greatest risk for RVF. Laboratory worker-acquired cases also occur. The person-to-person transmission of RVF has not been documented, but infected travelers may spread the virus to nonendemic countries, with potentially global implications for severe disease in livestock and humans.^{7,14}

CLINICAL MANIFESTATIONS

Humans are very susceptible to RVF virus. During the epizootics in South Africa, most veterinarians and many farmers engaged in work with sick sheep and cattle became infected. In most cases infection was linked to direct contact with the carcasses, tissues, and organs of animals that died of RVF. Transmission probably occurred by the aerosolized body fluids of the animals. Some patients gave no history of such contact; in these cases the infection was transmitted by mosquitoes or possibly acquired by drinking infected milk. The virus can be transmitted readily to laboratory personnel by direct contact with infected animals or by the respiratory route from aerosol droplet infection. Travelers from endemic areas may also acquire RVF, so a careful travel history should be ascertained.^{7,14}

The incubation period of RVF is 3 to 7 days. Infection may be asymptomatic or cause a febrile illness or fever of undetermined origin. Illness with RVF onset is sudden, with chills, myalgia, joint pain, dizziness, headache, and an influenza-like illness. A biphasic fever that lasts approximately 1 week may occur. Patients often feel nauseated and may vomit or complain of abdominal fullness and pain. The face is flushed, the conjunctivae are injected, and the tongue is furred. Icterus may develop. Bradycardia is present, and slight tenderness over the liver, which may be enlarged, can be present. Many patients become delirious, and some have hallucinations. In a small proportion (1% to 10%) of patients the infection is complicated by retinitis.²⁰ Late in the course of the illness or early in convalescence, unclear vision may be noted, and the patient may have a central blind spot. This visual defect is associated with a cotton-wool exudate on the macula, with permanent vision loss. Both eyes are involved occasionally, and the loss of vision

from retinal lesions is a severe handicap. These lesions gradually resolve, and the patient’s vision may return to normal; however, some people are left with permanent retinal scars and vision loss. Some investigators have suggested that possible immune or autoimmune factors are involved in the pathogenesis and contribute to the severity of RVF retinitis.²⁰

Meningoencephalitis manifested as intense headache, confusion, and stupor may occur as a complication in less than 1% of patients during or after the second wave of fever. Lumbar puncture relieves the headache. Cerebrospinal fluid shows slight pleocytosis, mostly of lymphocytes, a normal glucose level, and a slightly increased protein content. Antibody to RVF virus also may be demonstrated in the cerebrospinal fluid. Few patients with encephalitis die. Recovery usually is complete, but convalescence may be prolonged. Occasionally, the patient is left with permanent neurologic sequelae or vision loss. Hemorrhagic fever, a complication with a case-fatality rate of 15%, develops in approximately 1% of patients with RVF. The mortality rate was disproportionately lower in children than in adults during the 1977 Egyptian epidemic. In cases of severe illness, a hemorrhagic diathesis may develop that includes epistaxis, hematemesis, melena, and, sometimes, cerebral hemorrhage. Profuse gastrointestinal hemorrhage may be fatal. Jaundice may be evident.

Infection with RVF virus in pregnant women is also associated with miscarriages and fetal deaths.³ In addition fatal disease in the newborn associated with vertical transmission from the mother has been reported.^{1,3}

The human genes *TLR3*, *TLR7*, *TLR8*, *MyD88*, *TRIF*, *MAVS*, and *RIG-I* have been associated with severe symptoms of RVF in humans, and this finding suggests that certain genetic polymorphisms may contribute to the severity of disease.¹⁶

LABORATORY FINDINGS

The patient has initial leukocytosis that is followed by leukopenia. Profound thrombocytopenia and other defects in coagulation may be observed. Disturbance in liver and kidney function also may be documented. The diagnosis of RVF is clinically suggested when humans have an acute, severe, but short febrile illness at the same time that an epizootic with high mortality is occurring in sheep.

The laboratory diagnosis usually can be confirmed by isolation of the virus in mice or cell culture from blood during the early days of illness and, in fatal cases, from the liver. Immunohistochemical study of tissues from necropsy or biopsy samples also may provide the diagnosis. Because the virus is a biosafety level 4 pathogen, virus cultivation should be attempted only in restricted laboratories. Detection using polymerase chain reaction assays also may be performed under appropriate safety

precautions in specialized laboratories. Quantitative real-time polymerase chain reaction detection and quantification of RVF virus in serum appear sensitive and useful as routine diagnostic tests for identifying the virus in the early stage of the disease in individual humans, for identification of cases during outbreaks, and for follow-up of antiviral therapy.^{10,24} The development of serum antibodies can be demonstrated by immunofluorescence, immunoglobulin (Ig) M enzyme-linked immunosorbent assay, hemagglutination inhibition, complement fixation, and neutralization. In patients with encephalitis, RVF virus-specific IgM and IgG antibodies are detectable in cerebrospinal fluid.

TREATMENT

Treatment is symptomatic and supportive, with appropriate isolation precautions. When a hemorrhagic diathesis develops, treatment should be directed toward controlling bleeding. Transfusions of fresh frozen plasma and platelets may be beneficial for bleeding. Convalescent-phase plasma from survivors of RVF may also provide benefit and improve survival. There is no licensed specific antiviral therapy for RVF, but effective therapeutic agents are needed because of the serious human and veterinary threat of this virus.⁶ Ribavirin has activity against Bunyaviridae and is used to treat disease caused by hemorrhagic fever viruses.^{7,14} In addition, treatment with amantadine, rifampicin, and dexamethasone in a patient with encephalitis was reported.^{7,14}

PREVENTION

RVF is mainly a disease of adults and is usually acquired occupationally. It is a serious hazard faced by veterinarians, ranchers, and laboratory personnel in the course of their work. Because RVF usually is acquired by direct contact with the tissues of infected sheep and cattle, the risk for acquiring infection can be reduced by wearing gloves, protective masks, and goggles when postmortem examinations are carried out on animals that have died of unknown causes. Because of the value of domestic animals in many economically depressed areas of Africa, sheep and cattle often are housed within family compounds. Sick or dying animals usually are killed to salvage their meat. In this peridomestic environment, children also can be exposed to virus aerosols and readily become infected. Infection from a mosquito bite is also a mode of transmission for RVF, and for this reason the use of mosquito repellents and mosquito bed nets is recommended.

The primary strategy for preventing RVF in both humans and animals relies on vaccination of sheep and cattle, which are the amplifying hosts, and vaccination of humans in high-risk situations. Humoral immunity appears protective against RVF virus infection, but the role of cellular immunity is not clearly understood.²¹ Attenuated strains of the virus have been developed and used successfully on a mass scale to immunize livestock. These attenuated vaccines are associated with some abortions

in pregnant ewes and cows. An inactivated vaccine for livestock is safe and is in widespread use in Africa.²³

A live attenuated vaccine designated MP-12 was developed by passage of RVF virus in the presence of the mutagen 5-fluorouracil.¹⁸ The vaccine has proved safe for use in domestic livestock, does not produce abortions, and offers considerable promise as a veterinary and human vaccine. It is conditionally licensed for veterinary use in the United States.²¹ More recently an attenuated strain, designated clone 13, has been investigated and shown effective in protecting sheep without any noticeable adverse effects. Another strain, designated R566, derived from both clone 13 and MP-12 through reassortment, is also under investigation.^{7,13,15} Formalin-inactivated vaccine RVFV TSI-GSD-200 is being used to vaccinate military and laboratory personnel who are in contact with RVF virus.^{7,8,13,15} Virus-like particles generated by reverse genetics or expression vectors, as well as DNA vaccines, are in development.

191B ■ Crimean-Congo Hemorrhagic Fever

Gail J. Harrison

Crimean-Congo hemorrhagic fever (CCHF) is a serious and potentially fatal viral illness that often has hemorrhagic manifestations.^{3,32} The clinical entity as a tick-borne hemorrhagic fever and its viral origin were described first in Russia in the Crimean Peninsula by Chumakov in 1945. The agent was not propagated or available for study until 1967 and was further studied in 1969 in the Congo.^{35,38,39} Since then, CCHF virus has been reported from many countries in Eastern Europe, Central Asia, and Africa.^{9,35,38} The virus currently can be found in Africa, Asia, the Middle East, and Eastern Europe. During 2001, CCHF was diagnosed in patients in Kosovo, Albania, Iran, Pakistan, and South Africa. In the 21st century, outbreaks have become more frequent in the region of the former Yugoslavia, Turkey, and Iran.^{24,29} In 2010, an outbreak in India was reported.¹ Exposure to ticks and contact with the blood of infected livestock or people are the usual sources of human infection.

Travelers also should be evaluated for CCHF if they traveled to areas where CCHF transmission has occurred.²⁴

ETIOLOGIC AGENT

CCHF virus, the etiologic agent, is a member of the genus *Nairovirus* in the family Bunyaviridae. It is lethal to newborn mice after intracerebral inoculation. CCHF virus replicates in some vertebrate cell lines, but isolation in mice is more sensitive because the virus usually does not cause any discernible cytopathic effect under fluid overlay. Thus indirect methods such as immunofluorescence or reverse-transcriptase polymerase chain reaction must be used to detect CCHF viral antigen or nucleic acid in the cells. The complete genome of CCHF viruses isolated from geographically and climate diverse areas indicates that

distinct geographic lineages exist but also that these viruses are highly variable within lineages.^{5,11,27,31,39}

A relatively high level of viremia develops in persons with CCHF and persists for 6 to 8 days after onset of the illness.³⁵ Blood from acutely ill patients with CCHF is quite infectious, and numerous nosocomial infections have occurred in hospital personnel caring for patients with this disease.^{4,9,20} CCHF virus is relatively stable in blood and serum and has been recovered from specimens stored as long as 2 or 3 weeks at 4°C.

EPIDEMIOLOGY

CCHF virus is known to occur over a wide geographic area, including Eastern Europe, southern Europe, Central Asia, western China, the Middle East, India, and Africa (Fig. 191B.1).^{1,5,9,11,27,39} The global distribution of CCHF virus appears to be migrating and expanding. Because it is expected that future outbreaks may extend to new areas, increased surveillance and geographic mapping of this potentially lethal viral infection are needed. Most cases of the disease probably are unrecognized because of its sporadic occurrence and largely rural distribution or its occurrence in developing countries. It is often considered an occupational disease of health care workers and persons who work with or around animals. Travelers also may acquire CCHF and are at risk to import the infection.²⁴ It also is considered a possible bioterrorism agent.^{39,40}

The epidemiology of CCHF is complex and not fully understood because of the variety of tick and mammalian species that have been found to be naturally infected with the virus.³⁸ The *Hyalomma* spp. ticks have been incriminated in transmission of CCHF virus in the field, but the role of other ticks in transmission is also possible.⁵ The basic transmission cycle of CCHF virus varies from region to region, depending on the developmental stage and species of ticks involved

and their preferred mammalian hosts.³⁸ In addition, transovarial and transstadial transmissions of CCHF virus also have been demonstrated in some tick vectors. In general, human cases of CCHF usually are associated with periods of tick abundance and feeding activity.⁹ For example, in Eastern Europe, cases of CCHF typically occur between May and August, when the tick population is active. Models of global warming climate scenarios project that the northern limit of the tick range may increase and change the distribution of the disease.^{5,11} Humans usually acquire CCHF from a tick bite or from contact with blood or other tissues of infected livestock.^{9,35,38} Most patients have a history of contact with large domestic animals (farmers, abattoir workers, and veterinarians). Health care workers are another high-risk group.

Numerous CCHF health care–associated outbreaks have occurred in hospital workers and laboratory technicians.^{4,9,20,39} These persons usually have had direct contact with the blood of patients with CCHF. The mortality rate reported in secondary cases has been high, particularly in persons with needle-stick injury or those involved in management of patients with gastrointestinal bleeding.⁹

PATHOGENESIS

The pathogenesis of CCHF is not well understood, but the available evidence suggests that endothelial damage and dysfunction play important roles in the hemostatic failure.^{9,20,36} Excessive proinflammatory cytokine production, cytokine storm, and dysfunction of the innate immune response also appear to contribute to the disease process. Lymphocyte depletion also seems to occur.² CCHF sometimes leads to reactive hemophagocytic histiocytosis in children.^{7,26} Fluorescent antibody studies on organs in fatal cases of CCHF show a concentration of viral antigen in the reticuloendothelial cells of the liver and spleen, a finding suggesting that these cells are major sites of virus replication.³⁶ Other pathologic

changes observed at autopsy include generalized vascular lesions with endothelial damage that give rise to scattered focal hemorrhage and edema in most organs.⁹ In severe cases, dysfunction of the coagulation system and disseminated intravascular coagulation appear to be prominent features of the disease.

CLINICAL MANIFESTATIONS

The course of CCHF infection typically has four distinct phases: incubation, prehemorrhagic, hemorrhagic, and convalescent (Fig. 191B.2).^{9,8,36} The incubation period generally is 3 to 7 days. The prehemorrhagic phase begins suddenly with fever (39–41°C [102.2–105.8°F]), nausea, diarrhea, vomiting, myalgia, rash, and general toxemia. Patients usually are flushed, with red eyes associated with conjunctival and scleral injection. Children commonly have pharyngitis and tonsillitis as presenting signs.³⁷ Hepatosplenomegaly with hepatitis commonly occurs in as many as 30% of cases. Thrombocytopenia also occurs. This second phase lasts approximately 3 days (range, 1–7 days). The hemorrhagic phase usually begins between the third and fifth days of the disease and lasts only 2 to 3 days. The appearance is sudden and can vary from petechiae to large hematomas on the skin and mucous membranes. Profuse bleeding from the nose, gums, gastrointestinal and genitourinary tracts, and lungs can occur at this stage, resulting in tachycardia, shock, and, sometimes, death. Not infrequently, intraabdominal bleeding occurs during this third phase and causes acute pain; some of these patients are subjected to surgery because of suspected appendicitis or intestinal perforation. Hemorrhagic pleural effusions and cardiac manifestations may occur.^{14,16,33} Bradycardia may also occur and often is reversible.^{14,16,30} Fatality is higher in patients with diarrhea, melena, hematemesis, hematuria, and confusion at presentation.¹⁸ If the patient survives the hemorrhagic phase, convalescence begins about the 10th day, with a slow convalescent period lasting 2 to 6 weeks.⁹ Viremia is intense and prolonged in CCHF, especially in fatal cases, so blood from these patients should be treated with extreme care.

Pregnant women who acquire CCHF may transmit the infection to their fetus. Infection in the first trimester may result in miscarriage. Infections in pregnancy later in gestation may result in normal newborn delivery.^{6,13}

Leukopenia and thrombocytopenia are consistent features of CCHF and occur early in the disease.^{9,8,18} Other abnormal laboratory findings usually include elevated levels of serum aspartate and alanine aminotransferase, lactate dehydrogenase, bilirubin, creatinine, and urea. Fatality is associated with higher levels of aspartate aminotransferase, alanine

aminotransferase, and C-reactive protein levels and with prolonged coagulation tests such as prothrombin time and activated prothrombin time.¹⁸ Fibrinogen may be decreased, and fibrin degradation products may be increased. These laboratory values generally return to normal levels with the onset of convalescence.

DIAGNOSIS

A clinical diagnosis of CCHF is difficult to establish before the onset of hemorrhagic manifestations because the initial symptoms are nonspecific, and cases usually occur sporadically. The differential diagnosis of CCHF in children includes viral upper respiratory tract infections, brucellosis, periodic fever syndrome, and cellulitis associated with the tick bite.²¹ As a result of the frequency and severity of the abdominal pain associated with the prehemorrhagic and hemorrhagic phases of CCHF, the disease sometimes is misdiagnosed as appendicitis or gastric ulcer. Such patients may be subjected to unnecessary surgery, which can be fatal to both the patient and the attending medical personnel.^{4,9,35} Once hemorrhagic manifestations appear, the differential diagnosis should include erythema multiforme (Stevens-Johnson syndrome), leptospirosis, hemorrhagic fever with renal syndrome, Ebola virus infection, Lassa fever, Rift Valley fever, Q fever, and yellow fever, depending on the region of the world where the patient was exposed. Unusual complications of CCHF include hemorrhagic pleural effusions, and myocarditis.³⁰

A definitive diagnosis of CCHF can be made by isolating the virus from the patient's serum or by detecting viral nucleic acids by polymerase chain reaction during the first week of illness.³⁴ Molecular methods for diagnosis are being applied by many laboratories in endemic areas for accurate and timely diagnosis. However, performance of these molecular methods may vary depending on method used, type of CCHF virus strain tested, and the concentration of the virus in the sample.¹⁰ Immunoglobulin (Ig) G and IgM antibodies do not appear until 7 to 10 days after the onset of symptoms in nonfatal cases.^{35,36} Establishing the diagnosis early is critical for proper management of the patient and prevention of potential transmission to health care workers caring for the patient.

TREATMENT

Treatment of CCHF is largely supportive and should include immediate hospitalization and strict bed rest.^{9,35} High mortality rates (average, 30%) have been reported. Because death usually results from acute

blood loss and shock, patients may require transfusions of fresh blood, platelets, or plasma (or all three). Administration of immune plasma or CCHF-negative hyperimmune globulin obtained from convalescent donors can be used early in the course of the illness or for persons, such as hospital personnel, who are exposed to the virus inadvertently, especially if they reside in endemic areas.^{7,26,39} Therapeutic plasma exchange has also been successfully performed in selected patients. Ribavirin may be beneficial for treatment of CCHF, even in pregnant women, and especially if treatment is begun within the first 4 days of illness, and it is recommended by the World Health Organization.^{6,9,8,12,13} The mechanism of action is unknown. Ribavirin also has been shown to protect mice from lethal CCHF virus challenge.^{19,25,26} A World Health Organization report recommended intravenous ribavirin treatment for 10 days, with 30 mg/kg as an initial loading dose, then 15 mg/kg every 6 hours for 4 days, and then 7.5 mg/kg every 8 hours for 6 days.^{9,12,19,25} Oral ribavirin also has been reported to have potential benefit.^{12,19,25} In patients with CCHF associated with reactive hemophagocytic histiocytosis, administration of high-dose methylprednisolone, 5 to 30 mg/kg per day, fresh frozen plasma, and intravenous immunoglobulin has been shown possibly to be effective.⁷

PROGNOSIS

The mortality rate for CCHF has been estimated at 30%, but estimates have varied from 15% to 70%.^{9,35,38} These figures may be high because milder cases of the disease may not be recognized or reported. The illness associated with CCHF in children may be milder and less often fatal than the illness in adults. Factors predictive of fatality include clinical signs of melena, hemorrhage, and confusion, and laboratory findings of elevated transferase levels, elevated C-reactive protein value, elevated procalcitonin levels, CCHF viral load in serum, and high concentrations of interleukin-6 and tumor necrosis factor- α , as well as lack of virus-specific IgG humoral response and the presence of prolonged coagulation factors.^{17,18,22} These factors may help clinicians in countries with limited resources decide which patients may benefit from care in a tertiary care center. If the patient survives the hemorrhagic phase of the disease, recovery is complete, and permanent immunity results. Survivors may experience posttraumatic stress disorder, especially if they were critically ill and required care in an intensive care unit.¹⁵

PREVENTION

No vaccine of proven safety or efficacy for prevention of CCHF is licensed. However, an inactivated, suckling mouse brain-derived Bulgarian CCHF vaccine has been shown to produce anti-CCHF-specific T-cell activity and high levels of CCHF-specific antibodies.^{23,28} Personal protective measures, including insect repellents containing diethyltoluamide (DEET), are recommended for people living or working in heavily

tick-infested areas. People exposed occupationally to potentially infected animal blood should wear protective clothing and gloves to prevent skin contact with infected tissue or blood. Hospital personnel caring for patients with CCHF should follow barrier nursing and isolation protocols, which include use of gloves, gowns, face shields, and goggles.

Acknowledgment

I thank Robert B. Tesh for his contributions to this chapter in the previous editions of this text.

191C ■ Phlebotomus Fever (Sandfly Fever)

Gail J. Harrison

Phlebotomus fever is an acute, self-limited febrile illness of 2 to 4 days' duration that usually is acquired from the bite of infected phlebotomine sandflies. Phlebotomus fever also is known as sandfly fever, pappataci fever, and 3-day fever. Sandflies have sporadically been in Central Europe since the Holocene climate optima (c. 4500 BC). The disease is currently endemic in many areas of Central Asia, northern Africa, and southern Europe. Global warming is predicted to extend the distribution of sandfly fever into Central Europe.^{1,14} Both historically and currently, phlebotomus fever has been largely of military interest because the introduction of large numbers of susceptible troops into endemic areas often has resulted in epidemics of the disease.^{5,11} More recently, the disease has been reported with increasing frequency in civilian populations and in tourists visiting endemic areas. An outbreak of sandfly fever virus has been reported in Turkey.¹² Sandfly fever virus infection imported from Malta into Switzerland by travelers also has been reported.²⁰

In 1909, Doerr and associates first demonstrated that the causative agent of the illness was a virus transmitted by *Phlebotomus papatasi*. In 1954, Sabin successfully adapted the agent to mice and described two distinct serologic types, designated the Naples and Sicilian strains.^{22,23} Subsequently, 44 additional serotypes were isolated from various regions of the world; all these agents are included in the genus *Phlebovirus*, family Bunyaviridae. Although most of the phleboviruses probably are capable of producing human illness, the discussion here is limited to the three (Naples, Sicilian, and Toscana) that are associated most commonly with human illness. Rift Valley fever virus, which causes a severe disease acquired from the bite of infected mosquitoes or aerosol, and Toscana virus, a phlebovirus that causes meningoencephalitis, also are members of this genus and frequently cause a phlebotomus fever–like illness in infected persons. In addition, Saddaguia virus and sandfly fever Sicilian virus and Utique virus also are phleboviruses found in

association with sand flies.^{9,13} Some of these diseases are covered in more detail in other chapters.^{4,7,17,21}

ETIOLOGIC AGENT

The phleboviruses are RNA-containing viruses, spherical, and 90 to 100 nm in diameter.²² The Naples, Sicilian, and Toscana viruses produce a cytopathic effect, as well as plaques in Vero cells. A novel sandfly fever virus variant of the Sicilian virus, termed sandfly fever Turkey virus, has been identified by consensus polymerase chain reaction and sequencing methodology.¹² Most laboratory animals are not susceptible to infection with these viruses, although the viruses usually can be adapted to newborn mice by serial passage intracerebrally. For this reason, tissue culture is recommended for primary isolation of these agents, and molecular detection using real-time reverse-transcriptase polymerase chain reaction is useful for rapid detection and characterization.^{12,16}

EPIDEMIOLOGY

The geographic distribution of the Naples and Sicilian virus types in the Old World closely parallels that of their presumed vector, *P. papatasi* (Fig. 191C.1).²² Toscana virus has been isolated in Portugal, Spain, France, Italy, Greece, Croatia, Turkey, Corsica, Malta, and Cyprus and has been associated with two other peridomestic sandfly species, *Phlebotomus perniciosus* and *Phlebotomus perfiliewi*.^{3,7,6,13,22}

These phlebotomine species are tiny, sand-colored, biting flies that are 2 to 3 mm long. Because of their small size, they have little difficulty squeezing through ordinary screens and mosquito netting. They usually are nocturnal, and only the female bites. Sandflies move in short hops and usually do not travel more than a few hundred meters from their resting and breeding sites. During the day, peridomestic species such as *P. papatasi* and *P. perniciosus* rest in dark corners and crevices, often within houses. The larvae develop in loose soil and organic debris in stone walls, animal sheds, privies, open wells, and gardens. Because of their indoor habits, these peridomestic species are quite vulnerable to residual insecticides.

In Central Asia and the Mediterranean region, sandflies are active during the late spring and summer. The incidence of phlebotomus fever follows the same seasonal pattern. Global warming patterns are predicted to alter the epidemiology of sandfly fever in the future.^{1,14}

Many phlebotomus fever viruses appear to be maintained in the sandfly population by transovarial (vertical) transmission.²² Thus sandflies appear to serve as both vectors and reservoirs of these viruses. Unlike most other arboviruses, whose activity depends on the presence of susceptible and viremic vertebrate hosts, phlebotomus fever viruses are

probably active continuously during each sandfly season, regardless of the immune status of the local human population. Serologic studies of persons living in endemic areas of the disease indicate that most of the residents are infected early in life.^{22,23} In these communities, sporadic cases of phlebotomus fever occur in children because most of the adult population is already immune. However, because of the benign nature of the disease, its sporadic occurrence, and its similarity to many other viral diseases of childhood, most cases are unrecognized. When large numbers of susceptible persons (e.g., soldiers, tourists, refugees) enter an area where phlebotomus fever is endemic, however, bite transmission occurs, and an epidemic of the disease quickly ensues.^{10,22}

CLINICAL MANIFESTATIONS

The incubation period for phlebotomus fever averages 3 to 5 days.^{2,22} The influenza-like illness begins suddenly with fever, severe frontal headache, retroorbital pain, red eyes from conjunctival injection, photophobia, malaise, anorexia, nausea, vomiting, myalgia, and lower back pain.¹⁸ The face may be flushed, but a true rash is absent. The disease is self-limited, and symptoms usually disappear within 1 to 3 days; however, a general feeling of weakness and depression often occurs for a week or more after the illness.^{18,19}

Meningitis and meningoencephalitis with Toscana virus infection have been described with increasing frequency in southern Europe.^{2,4,7,6} In addition to the classic symptoms of phlebotomus fever, these patients exhibit nuchal rigidity, a positive Kernig sign, a clouded sensorium, and, occasionally, nystagmus and tremor. To date, no deaths have been recorded. Childhood cases of the meningoencephalitic form of Toscana virus infection have been reported,² but this form of the infection occurs more commonly in adults.

One attack of phlebotomus fever usually confers lifelong immunity against the infecting virus type but not against heterologous serotypes.¹¹ For this reason, second cases of the disease have been reported in the same person in areas where two or more virus serotypes are active.

Marked leukopenia usually is observed in patients with phlebotomus fever.¹ It is characterized by initial lymphopenia, followed by protracted neutropenia (Fig. 191C.2). In patients with central nervous system involvement, pleocytosis and an elevated protein content are observed in the cerebrospinal fluid.

PATHOLOGY

Fatalities caused by phlebotomus fever have not been reported, and little is known of the pathologic changes produced by these viruses.

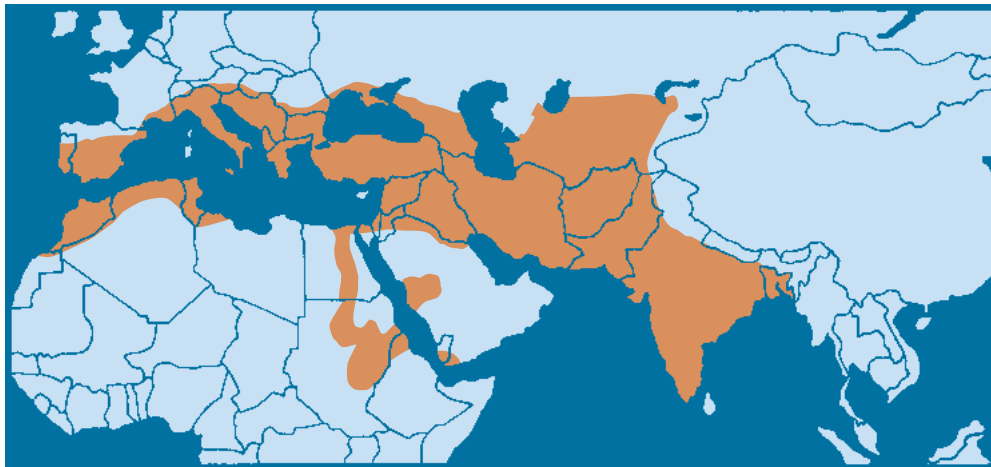

FIG. 191C.1 The known geographic distribution of *Phlebotomus papatasi*, the presumed vector of sandfly fever (Naples and Sicilian types), in Central Asia, the Mediterranean region, and adjacent areas of Africa. (Modified from Tesh RB, Saidi S, Gajdamovic SJ, et al. Serological studies on the epidemiology of sandfly fever in the Old World. *Bull World Health Organ.* 1976;54:663–674.)

FIG. 191C.2 Mean total white blood cell (WBC) count as well as absolute neutrophil and lymphocyte counts in 11 adult volunteers inoculated (day 0) with the Sicilian strain of sandfly fever virus. The average incubation period in the subjects was approximately 70 hours. (Modified from Bartelloni PJ, Tesh RB. Clinical and serologic responses of volunteers infected with phlebotomus fever virus [Sicilian type]. *Am J Trop Med Hyg.* 1976;25:456–462.)

DIAGNOSIS

The diagnosis of phlebotomus fever often can be made on the basis of clinical and epidemiologic evidence. A sudden outbreak during the summer months of a short febrile illness with severe headache and marked leukopenia in visitors or other newcomers to an endemic area where sandflies are abundant should suggest the disease. Depending on the region, the differential diagnosis may include dengue, West Nile fever, malaria, influenza, and numerous other respiratory tract and enteroviral infections.

Transient (24–36 hours), low-level viremia occurs during this illness; therefore, isolation of the virus from blood is unusual. In a few instances, Toscana virus has been isolated directly from the cerebrospinal fluid of persons with central nervous system symptoms.⁴ Molecular techniques (reverse-transcriptase polymerase chain reaction) have been described for direct detection of Toscana and Sicilian virus and clinical diagnosis of aseptic meningitis caused by Toscana virus and for detection of a novel Turkey variant virus in clinical samples.^{7,12,16,18} However, one of the problems with using molecular methods to detect phleboviruses directly in clinical material is the wide genetic diversity among members of each serotype. In addition, limited sequence data are available for many of the phleboviruses. At present, serologic tests offer the simplest

method for establishing a specific diagnosis of phlebotomus fever. Antibodies are present in serum 7 to 14 days after infection and can be demonstrated by immunofluorescence,² enzyme immunoassay,¹¹ or neutralization testing.² A fourfold rise in antibody titer from acute to convalescent sera or the presence of specific immunoglobulin M antibodies provides presumptive evidence of a recent phlebotomus fever virus infection. At present, these serologic tests are not generally available and usually are performed in only a few arbovirus laboratories.

TREATMENT

There is no licensed specific antiviral treatment available for sandfly fever. However, ribavirin inhibits a late step of the virus replicative cycle and, when combined with interferon- α , has shown a synergistic antiviral effect.⁸ In addition, the pyrazine carboxamide derivatives T-705 (favipiravir), T-1105, and T-1106, which are compounds with broad activity against RNA viruses, for treatment of phlebovirus infections, have been evaluated.¹⁵ Treatment is symptomatic, currently, and hospitalization usually is not necessary, except in patients with more severe cases of Toscana virus infection. Occasionally, pain relievers are required to relieve the severe headache associated with the disease.

PROGNOSIS

Phlebotomus fever is a self-limited, nonfatal illness. Recovery is complete.

PREVENTION

Control measures are directed primarily against the vector. Household spraying with residual insecticides is quite effective in reducing peridomestic sandfly vectors and controlling the disease. The use of personal insect repellents (e.g., diethyltoluamide) and fine-mesh bed nets is also effective in avoiding sandfly bites.

Acknowledgment

I thank Robert B. Tesh for his contributions to this chapter in the previous editions of this text.

191D ■ Oropouche Fever

Francisco de Paula Pinheiro • Amelia P.A. Travassos da Rosa • Pedro Fernando da C. Vasconcelos • Gail J. Harrison

Oropouche (ORO) fever is currently only in Central or South America and is one of the most important arboviral infections in the Brazilian Amazon. ORO fever is an emerging arbovirus infection that causes sporadic outbreaks in Central and South America that are characterized by an acute febrile illness accompanied by headache, myalgia, arthralgia, and other systemic symptoms.^{13,23,35} The symptoms of ORO fever overlap with several other emerging arboviral-like illnesses, such as dengue, chikungunya, West Nile virus, and Mayaro virus, a finding suggesting

that an emerging mnemonic of ChikDenMayZikOrov should be used to address the similarity of these infections, which may infect returning travelers from endemic areas, and to include them all in the differential diagnosis of acute febrile illness with headache, arthralgia, and rash.²³

The initial symptoms of ORO fever usually recur a few days after the end of the first febrile episode, at which time they generally are less severe. Aseptic meningitis may develop in some patients. Patients make a full recovery, without any apparent aftereffects, even in the most

serious cases. No fatalities have been confirmed as being attributable to ORO fever. One of the most striking characteristics of ORO virus (OROV) is its ability to produce epidemics in urban population centers, most of which reportedly have occurred in the Brazilian Amazon region, although some have occurred in other countries in northern South America, Central America (Panama), and the Caribbean region (Trinidad and Tobago). Many of these outbreaks have had a major impact on the stricken cities.

The first case of the disease was described in 1955 in a resident of Vega de Oropouche, Trinidad, from whose blood the agent was isolated.² The disease was detected again in 1961, this time in the city of Belém, in northern Brazil, where it caused an epidemic that affected at least

11,000 people.²⁶ This epidemic was followed by many other epidemics, several of an explosive nature, in urban population centers throughout the Brazilian states of Pará, Amapá, Amazonas, Tocantins, Maranhão, Rondônia, and Acre.^{12,17,26,30,31,32,38,41} Outside Brazil, epidemics of ORO fever were reported in Panama in 1989 (E. Quiroz and associates, Panama, unpublished data, 1989) and in the Amazon region of Peru in 1992⁵ and in 1994 (Ministry of Health, Peru, and US Naval Medical Research Institute Detachment [NAMRID], Lima, unpublished data, 1994) (Fig. 191D.1). On June 22, 2010, the Pan American Health Organization reported an outbreak of OROV infection in the northern Amazonian region of Peru. As of mid-June 2010 the Peruvian Ministry of Health reported a total of 282 cases, of which 41 cases were confirmed and

FIG. 191D.1 Phylogenetic tree based on the complete nucleotide sequence of the N gene (693 nt) of 96 OROV strains isolated from different hosts, locations, and periods. The main phylogenetic groups are represented by the genotypes I (red), II (dark blue), III (green), and IV (light blue). The values above the main nodes represent the dates of emergence of common ancestors expressed in years from 2009. Arrows indicate the probable date of emergence of genotypes I, II, III, and IV. **MRCA**, Most recent common ancestor. The numbers inside the parentheses are its value for high population density (HPD) 95%. The numerical data in the bar represent the time scale of molecular dating. (From Vasconcelos HB, Nunes MRT, Casseb LMN, et al. Oropouche fever virus: molecular epidemiology and evolution. *Emerg Infect Dis*. 2011;17:800–806.)

241 were probable. The outbreak has centered on Bagazán, in the district of Pachiza in the department of San Martín, and was the first outbreak to be reported in the region.²² In January through March 2016, an outbreak of 57 confirmed cases of ORO fever occurred in towns in the northern part of the Cusco Region, in the Amazon Rainforest.⁴⁵ In February 2016, a mixed outbreak of dengue fever and ORO fever occurred in Peru. Because the competent vector for OROV has a broad geographic distribution, the risk of cases being identified in other countries is now significant, and the World Health Organization and the Centers for Disease Control and Prevention will monitor the status of OROV infection globally.

ETIOLOGIC AGENT

ORO fever is caused by OROV, which belongs to the genus *Orthobunyavirus* of the family *Peribunyaviridae*.^{32,37} The virus has enveloped spherical particles 90 to 100 nm in diameter; the capsid has helical symmetry; and the single-stranded, negative-sense RNA contains three segments, designated large (L), medium (M), and small (S) RNA.^{18,32} Complete nucleotide sequences have been determined for all three RNA segments.^{3,36,42} Phylogenetic analysis based on S RNA (N gene) has revealed that all OROV strains form a monophyletic group consisting of four distinct lineages (Fig. 191D.2).⁴⁰ Lineage I contains the prototype strain from Trinidad and most of the Brazilian strains; lineage II contains the Peruvian strains isolated between 1992 and 1998 and strains from western Brazil isolated in 1991, as well as isolates obtained more recently from Amapá and Pará states in the eastern Amazon; lineage III comprises strains isolated from Panama during 1989³⁶ and strains isolated in the Brazilian states of Acre, Pará, and Rondônia (Amazon region) and Minas Gerais (Southeast region); and, finally, lineage IV was detected only in a strain isolated during an outbreak that occurred in Manaus, Brazil, in 1981.⁴⁰ Antigenically, OROV belongs to the Simbu group, which, in turn, is part of the Bunyamwera supergroup of arboviruses. The virus has a hemagglutinin that is active against geese erythrocytes, and it can

be recovered from infected hamster serum treated with acetone (A. P. A. Travassos da Rosa, Belém, unpublished data, 1969). Intracerebral and intraperitoneal inoculation of OROV into baby mice and intracerebral, intraperitoneal, and subcutaneous inoculation of the virus into adult hamsters produce lethal infections. The virus replicates in numerous cell cultures, including Vero, BHK-21, and primary chicken embryo fibroblast, and it causes a cytopathic effect.³² The agent is sensitive to the action of sodium deoxycholate.¹⁶

EPIDEMIOLOGY

Geographic Distribution

Thus far the only reported cases of ORO fever have occurred in Argentina, Brazil, Panama, Peru, and Trinidad (see Fig. 191D.2). However, most cases have been limited to the Brazilian Amazon region, with none reported in other areas of Brazil.

With a few exceptions, all episodes of ORO fever have been in the form of urban epidemics, including those in Belém and Manaus, the largest cities in the Brazilian Amazon region. The city of Belém, capital of Pará, was struck by three major epidemics during a 20-year period. The city of Santarém and surrounding villages also were affected by a major epidemic in 1974 and 1975.³⁰ The first epidemics that occurred outside Pará, those striking the cities of Manaus and Barcelos in Amazonas⁸ and the city of Mazagão in what was then the Amapá Territory, were reported early in the 1980s.²⁴ After a period of quiescence lasting until 1988, new outbreaks of the disease struck the cities of Porto Franco and Tocantinópolis in the states of Maranhão and Tocantins, respectively.⁴¹ The next reported epidemics occurred in 1991, this time in more distant locations, namely, in the cities of Ariquemes and Ouro Preto D'Oeste in Rondônia; the epidemic's impact on these cities was so great that it was reported in the national press. In 1994, another outbreak involving at least 6000 people was recorded in Serra Pelada in Pará.³⁸ Other outbreaks were recorded in 1996 and affected at least five urban centers in the states of Pará, Amazonas, and Acre.³¹ Thus,

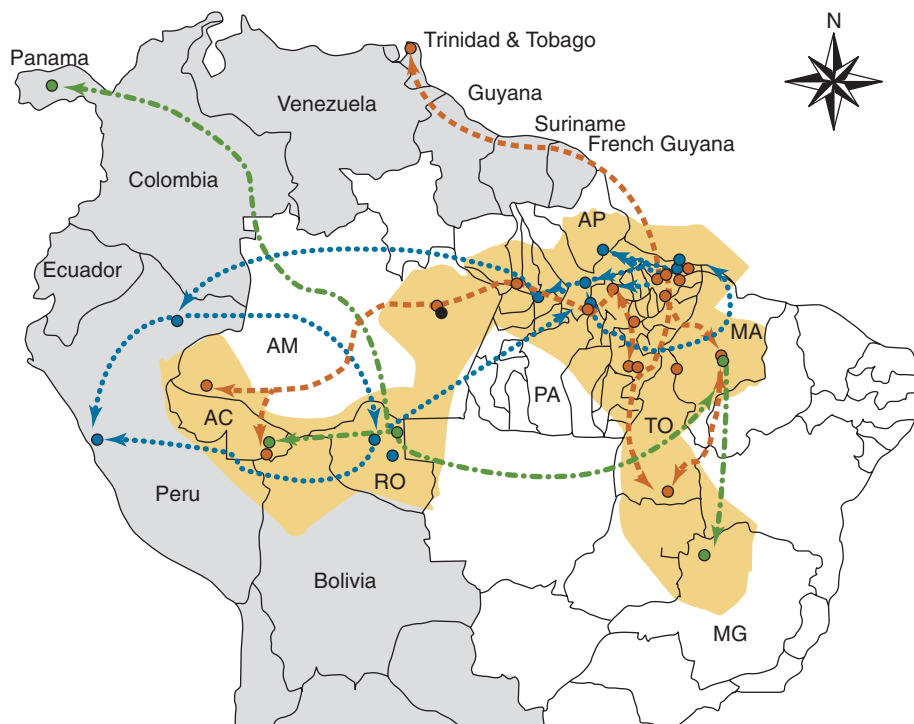

FIG. 191D.2 Geographic dispersion of OROV genotypes in the Americas between 1955 and 2009 based on the N gene genetic data. Red line, dispersion route for genotype I; blue line, dispersion route for genotype II; green line, dispersion route for genotype III; black dot, genotype IV. Coverage area of the OROV in Brazil: AC, Acre; AP, Amapá; AM, Amazonas; MA, Maranhão; MG, Minas Gerais; PA, Pará; RO, Rondônia; TO, Tocantins. (From Vasconcelos HB, Nunes MRT, Casseb LMN, et al. Oropouche fever virus: molecular epidemiology and evolution. *Emerg Infect Dis.* 2011; 17:800–806.)

during 1961 to 1996, more than 30 epidemics of ORO fever were recorded in Brazil. Several small outbreaks also were recognized in Canaã dos Carajás in 2003 and in Tapará Village at Porto de Moz in 2004, both municipalities in Pará.^{4,21} In April of 2006, a large epidemic of ORO fever occurred in northeastern Pará that affected several municipalities. Autochthonous cases of ORO fever also were diagnosed in the municipalities of Magalhães Barata, Maracanã, Marapanim, Igarapé-Açu, São Francisco do Pará, and Viseu. A retrospective serologic study conducted among inhabitants of urban and rural communities of the municipality of Magalhães Barata showed that 320 of 631 persons had immunoglobulin (Ig) M OROV antibodies detected by enzyme-linked immunosorbent assay, thus suggesting that approximately half of the 8000 inhabitants had been infected. In this episode, several isolates were obtained and sequenced, and the OROV genotype II was recognized.³⁹ The last recorded epidemic in those municipalities occurred in 1980.¹² In 2016, The Ministry of Health of Peru reported 57 nonfatal cases of ORO fever in towns in the northern part of the Cusco Region, in the Amazon rainforest.⁴⁵

Serologic surveys^{12,24,28,31} estimated that more than 360,000 people were infected during this period (P.F.C. Vasconcelos, M.R.T. Nunes, unpublished data, 2006). However, this estimate actually is quite conservative because the incidence of this viral disease was not computed in many major outbreaks (Belém, 1968; Porto Franco and Tocantinópolis, 1988). In 2009 a large epidemic of ORO fever was reported in Mazagão, Amapá, and was caused by genotype III (P.F.C. Vasconcelos, unpublished data, 2009); the last report of ORO fever in the municipality occurred in 1980. Possibly more than a half million people in the Brazilian Amazon region may have been infected with OROV since the beginning of the 1960s.

In addition to the aforementioned epidemic areas, countless small villages scattered throughout virtually the entire Amazon region have residents who show hemagglutination-inhibition antibodies against OROV. In general, the prevalence of these antibodies is less than 3%, with the exception of Ilha de Gurupá, where it is 10.7%.³¹ An OROV strain was isolated from a novel primate host (*Callithrix* spp.) in Arinos in Minas Gerais in southeastern Brazil,²⁰ thus extending the enzootic area farther to southern Brazil.

Outside Brazil, outbreaks were reported in Panama and Peru. The outbreak in Panama occurred in 1989 in the village of Bejuco, which is located approximately 50 km west of the capital (E. Quiroz and associates, Panama, unpublished data, 1989). The first epidemic in Peru was reported in 1992 in the city of Iquitos in the Peruvian Amazon region.⁹ Subsequently, an outbreak occurred in Puerto Maldonado, Madre de Dios, also in the Peruvian Amazon region (Ministry of Health, Peru, and NAMRID, Lima, unpublished data, 1994). Studies performed in Peru suggested that transmission of OROV occurs continuously in the population of the city of Iquitos and surrounding villages.⁴³ Evidence of immunity to OROV was detected in nonhuman primates in Colombia, a finding suggesting the presence of OROV in that country as well.¹⁶ OROV has been detected by reverse-transcriptase polymerase chain reaction assay from febrile persons in Jujuy, northern Argentina (P. F. C. Vasconcelos, unpublished data, 2009). The nucleotide sequencing of S RNA showed that the Argentinian strains belonged to genotype IV.

Incidence

A significant characteristic of ORO fever is the exceptionally high attack rates seen during several outbreaks. Although incidence rates varied in different outbreaks, a rate of 30% was quite common. The proportion of those infected who had overt disease is not known with certainty, but in one epidemic clinical disease developed in 63% of those infected.¹²

Sex-specific attack rates vary. Rates in female patients were slightly higher than those in male patients in villages in the Bragantina area, in eastern Pará, which was struck by the virus in 1979,¹² and the opposite was true in the outbreak in Belém that same year. However, in the reported epidemics in Santarém, the infection struck female patients twice as often as male patients.¹¹ ORO fever affects all age groups, although in certain outbreaks the incidence was higher in children and young adults.

Diffusion of Epidemics

As indicated earlier, ORO fever epidemics have struck different locations at varying intervals. However, many outbreaks have been marked by

bona fide epidemic sweeps, with countless numbers of villages within a particular geographic area affected by the virus. This diffusion phenomenon was observed in Bragança in 1967, in Santarém in 1974 and 1975, and even more dramatically in Belém and in the Bragantina area from 1978 to 1980 (where at least 10 towns were stricken), as well as in Rondônia in 1991. Spread of the virus most likely is attributable to the movement of viremic persons throughout areas in which the virus vector is present.

Seasonal Fluctuation

Most epidemics of ORO fever typically occur during the rainy season, which, in the case of Pará in Brazil, corresponds to the period between January and June. However, many epidemics have extended into the dry season, although with less intensity. The seasonal nature of ORO fever most likely is linked to the higher density of populations of *Culicoides paraensis*, commonly known as the biting midge, the urban virus vector, in months with higher levels of rainfall, combined with a higher concentration of exposed individuals. Downward trends in epidemics of ORO fever generally are associated with the arrival of the dry season and the resulting lower density of biting midge populations and smaller numbers of exposed persons.^{18,33}

Endemic Transmission

During interepidemic periods, isolated cases of ORO fever undoubtedly occur in Brazil but remain undiagnosed. Although no systematic studies have been conducted to investigate endemic transmission of OROV in Brazil, seroepidemiologic investigations have indicated that the prevalence of anti-OROV antibodies in humans is 0% to 2% in areas where endemic transmission has not been reported,³¹ but it increases to 17% to 44% after outbreaks.^{11,18,32} These data suggest that endemic transmission of OROV is quite low in Brazil.

Transmission Mechanism

Laboratory studies and broad-based surveys conducted by the Evandro Chagas Institute of Belém during the course of epidemics point to the importance of the insect *C. paraensis* in the Ceratopogonidae as the urban vector for OROV.^{25,29} These tiny insects, commonly known as maruins (biting midges) in the Amazon region, are active during the day, particularly in the late afternoon hours. They crave human blood and bite people inside as well as outside their homes.^{15,20,34} The disease is transmitted by inoculation of the virus into exposed individuals by bites of infected midges.

Transmission Cycles

Studies conducted by the Evandro Chagas Institute³¹ suggest that OROV is perpetuated in nature through two different cycles, namely, an urban cycle and a wild cycle. In the urban or epidemic cycle, the virus is transmitted from person to person by the bite of *C. paraensis*. One of the most conclusive pieces of evidence attesting to this assertion lies in demonstration of the ability of *C. paraensis*, after feeding on the blood of viremic patients, to transmit the virus to hamsters bitten by the midges 5 or more days later.²⁹ Moreover, these midges typically are found in high densities during periods of epidemics. They breed mostly in the decomposing trunks of felled banana trees, in rotting husks of cocoa beans,¹⁴ and in piles of detritus formed in tree hollows.¹⁹ They are scattered throughout tropical and subtropical areas of the Americas.¹⁹

Attempts to transmit the virus from one hamster to another through the bite of the *Culex quinquefasciatus* mosquito (a species commonly found in urban areas throughout the Amazon region) demonstrated that the virus was transmitted only in the presence of extremely high levels of viremia, which rarely occurs in infected humans.²⁵ Thus this finding virtually rules out all likelihood that the epidemic vector is *C. quinquefasciatus*. Curiously, the virus isolation rate from *C. paraensis* during periods of epidemics is only one in 12,500,¹⁸ a finding suggesting that it is a low-efficiency vector. Apparently, humans are the only vertebrates in the urban cycle of OROV because studies of domestic animals conducted during the course of numerous outbreaks ruled out the possibility that these animals play an amplifying role.

As far as the wild, silent cycle of the virus is concerned, evidence suggests that among vertebrates, the *Edentata* (sloth), nonhuman

primates, and possibly certain species of wild birds serve as hosts. Although to date OROV has been isolated from mosquitoes (from a single pool of *Aedes serratus* in Brazil and once from *Coquillettidia venezuelensis* in Trinidad^{2,27}), the possible involvement of biting midges in the wild cycle of the virus nonetheless should be investigated.

The link between the two cycles most likely is humans themselves, who, after contracting the infection in enzootic forested areas and then returning to an urban setting during the viremic phase, become a source of infection for biting midges. The virus replicates in the tissues of biting midges, which, after the extrinsic incubation period, bite and infect exposed individuals. These individuals, in turn, serve as a source of infection for other midges, thereby forming a chain of transmission resulting in the unleashing of an epidemic.

Incubation Period

Observations conducted during numerous epidemics suggest that the incubation period ranges from 4 to 8 days. A laboratory worker who accidentally was infected orally exhibited symptoms of the viral disease 3 days later, and another technician fell ill 4 days after being infected, probably through the respiratory route.³¹

Transmissibility Period

The blood of infected patients is infectious to *C. paraensis* for the first 3 or 4 days after the onset of symptoms, when the level of viremia is high enough to infect the midges. Experimental studies have shown the length of the extrinsic incubation period to be 5 days or more.²⁹ The virus is not transmitted directly from one person to another.

Ratio of Symptomatic Cases

A prospective study conducted in the city of Santa Isabel in Pará in Brazil during the course of the epidemic of 1979 showed the ratio of symptomatic to asymptomatic cases to be roughly 2:1.¹² The study was performed during the period from March through June of that year. It involved 274 persons exposed to the virus who were monitored by clinical examination and laboratory testing on a weekly basis throughout the study. By the end of the study period, 78 (28.5%) of these persons had serologic evidence of OROV infection, with clinical manifestations of the disease developing in 49 (63%) of the 78.

CLINICAL MANIFESTATIONS

In most cases of ORO fever, the infection takes the form of an acute febrile episode, which runs its course. However, certain patients may show typical signs and symptoms of aseptic meningitis, which also runs its course without complications.

Classic Febrile Form

This form of the disease is characterized by the sudden onset of symptoms after an incubation period ranging from 4 to 8 days. The first symptoms to appear are fever, headache, chills, dizziness, muscular pain, arthralgia, and photophobia. Retroocular pain and conjunctival congestion also may be present. In addition, some patients have nausea, which may be accompanied by episodes of vomiting. Not uncommonly, patients have severe anorexia and insomnia. At times, cough and coryza are present as well, although these manifestations may be attributable to intercurrent infections. Certain patients complain of fleeting burning or stinging sensations in different parts of their body. The presence of an exanthem is a rare finding. Two laboratory workers who were infected accidentally reported a longer and heavier menstrual flow than usual.^{30,31} The fever can be quite high, 39°C or 40°C (102.2°F–104°F), and in some cases it may be higher than 40°C. The headache usually is localized in the front or back part of the head, although it also may be diffuse. It generally is severe and, in some cases, may not respond readily to common analgesics. Generalized myalgia is present and sharpest in the neck, along the vertebral column, and in the area of the sacrum. The pain may be extremely severe. Patients generally describe feeling as though their body had been crushed or they had been beaten. Usually, generalized arthralgia also is present. Certain patients have dizzy spells so severe that in some cases they collapse. Any epigastric pain generally is mild. Patients have no sign of jaundice, hepatomegaly, or splenomegaly. Occasionally, swollen lymph

nodes are detected in the submaxillary and occipital regions, and these findings could be totally unrelated to the viral infection.

The intensity of the clinical symptoms varies. In some cases, the symptoms are quite severe and even may cause prostration, whereas in others, they can be rather mild. Many patients are bedridden and, during epidemics, flood area hospitals, thus causing serious overcrowding.

The acute phase of the disease generally lasts 2 to 5 days but can be as long as a week. The myalgia, conversely, may persist for 3 to 5 days after the fever has disappeared. Some patients report having prolonged asthenia for as long as a month. Certain patients complain of a persistent headache lasting up to several weeks. No human deaths have been attributed to OROV infection.¹⁸

Nearly 60% of all patients have one or more recurrences in the first or second week after disappearance of the manifestations of the acute phase of the disease.^{12,24,31} Relapses may take the form of reappearance of all the acute-phase symptoms of the disease, or they may be limited strictly to fever, asthenia, and dizziness. In some reported patients, relapses were accompanied by a urinary tract infection of bacterial origin. An abscess, most likely bacterial, developed in the oropharynx of one particular patient approximately 10 days after recovery from the original febrile condition. In some cases, patients may have a series of relapses during a period of 2 to 3 weeks.³¹ All attempts to isolate OROV during relapses have failed.

Observations made during the course of the 1980 outbreak in Belém revealed that an exanthem developed in approximately 5% of all laboratory-confirmed cases.²⁴ The exanthem appeared between the third and sixth day after onset of the fever, disappeared 2 or 3 days later, and mainly involved the thorax, back, arms, and legs.^{24,28} During the outbreak in Manaus, many patients exhibited a maculopapular exanthem beginning on the torso and spreading to the upper and lower extremities.⁵ In another rare case, a 4-year-old child whose infection was confirmed by serodiagnosis experienced nystagmus, generalized tremors, and somnolence.¹² These symptoms lasted approximately 8 days, and the child apparently made a full recovery.

The effects of ORO fever on pregnancy are unknown. The only available data in this regard come from studies conducted in Manaus of nine pregnant patients, two of whom, both in the second month of pregnancy at the time, had miscarriages.⁵

Aseptic Meningitis

At first, patients exhibit manifestations typical of the initial acute phase of the infection. As the illness progresses, a few days later the headache and dizziness become increasingly severe, and some patients begin to experience other neurologic symptoms, generally during the second week of the illness, that lead them to seek medical care. The main complaints cited by patients are fever, extremely severe headache in the back of the head, and dizziness. Approximately one-third of all patients complain of nausea and vomiting. Some patients have moderate lethargy. They also may have trouble holding themselves upright. Some patients complain of double vision or diplopia. They generally try to keep from moving their heads to avoid aggravating their pain. In most cases, physical examination of these patients reveals varying degrees of stiffness of the neck but no signs of paresis or paralysis. Some patients experience nystagmus. Despite the seriousness of these neurologic symptoms, patients make a full recovery. Electroencephalograms taken of four patients showed no abnormalities. The incidence of meningitis in patients who seek medical care is less than 5%.²⁷

PATHOGENESIS

Little is known about the pathogenesis of ORO fever. The viral agent produces a systemic infection in humans that induces viremia during the first 2 days of illness.¹⁰

By the third day, the rate of viremia drops to 72%, and it falls to 44% and 23% by the fourth and fifth days, respectively. Viremia titers generally are higher than 3.0 log₁₀ median lethal dose/0.02 mL in mice, with approximately 10% of patients exhibiting virus titers as high as 5.0 to 5.3 during the course of the first 2 days of their illness. By the third day, virus titers are 1 log lower than in the first 2 days, and titers plummet by the fourth day.²⁹

Similarly, little is known about the pathogenesis of relapses, which occur commonly. That no sign of viremia could be detected in any of the countless patients examined during relapses is noteworthy.

The finding that OROV is capable of causing aseptic meningitis, combined with isolation of the virus from the cerebrospinal fluid (CSF) in one patient with meningitis,²⁷ suggests that the virus has the ability to penetrate the blood-brain barrier. With no known confirmed fatalities attributable to OROV, no data are available on the possible organic lesions caused by this agent in humans.

Laboratory tests on young hamsters inoculated with OROV showed that the virus has essentially hepatoviscerotropic properties, with isolated necrosis of hepatocytes or focal necrosis and the involvement of Kupffer cells exhibiting reactive hyperplasia; animals invariably succumb to the infection. In newborn mice the virus exhibits marked neurotropism, and animals show signs of focal encephalitis within 24 to 48 hours after being inoculated.⁴

LABORATORY FINDINGS

Leukopenia associated with neutropenia is found commonly, although in certain cases moderate leukocytosis may be present. The leukopenia can be severe, with reports of leukocyte counts as low as 2000/mm³. No signs of cell abnormalities are present. Aspartate and alanine aminotransferase levels are normal or may show a moderate increase, but in no case do they exceed 135 units/mL of serum. Platelet counts usually are normal but occasionally may be slightly low. The erythrocyte sedimentation rate and levels of urea, creatinine, and glucose in blood are normal, as are urine test results.²⁹

The CSF of patients with aseptic meningitis shows pleocytosis and an increased concentration of protein.²⁷ The cell count varies from 7 to 310 cells/mm³ of CSF; both segmented and mononuclear cells are present, with a predominance of segmented cells. In one case the cell count in CSF fell from 130 to 30 cells/mm³ in a 1-week period, and another patient's cell count fell from 70 to 10 cells/mm³ over a 3-week interval. In general, a moderate increase in protein levels occurs in the CSF, although one patient's protein level was more than 100 mg/mL. Glucose levels remain normal. The viral RNA from the causative agent has been detected in the CSF of patients with meningoencephalitis associated with ORO fever, as well as OROV-specific IgG and IgM antibodies.⁶

DIAGNOSIS

Specific confirmation of the infection is made by isolating the virus from a patient's blood or by performing OROV-specific serologic assays.^{7,32} To isolate the virus, blood samples need to be taken during the first 5 days of the illness, preferably in the first 2 days, when viremia is present in virtually all cases. The virus can be isolated by intracerebral or intraperitoneal inoculation of serum from infected patients into baby mice or young hamsters (in this case, subcutaneous inoculation can be used as well). Viral isolates also can be recovered in different cell cultures, such as Vero and BHK-21. The virus is identified by complement fixation or neutralization using OROV-specific ascitic fluid or antisera. Serodiagnosis is accomplished by the demonstration of an increase in antibody in paired serum samples taken during the acute and convalescent phases of the disease by hemagglutination inhibition, complement fixation, or neutralization. A positive IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) on a single serum sample provides a presumptive diagnosis of recent infection, particularly in the presence of a clinical picture consistent with the disease; the test result usually is positive after the fifth day of illness. A rapid and highly sensitive one-step TaqMan reverse-transcriptase polymerase chain reaction assay has been described for detection of OROV and certain other orthobunyaviruses; it was found to be more sensitive than the established nested polymerase chain reaction system.⁴⁴ A recent real-time RT-PCR was developed and has been used to diagnosis OROV and IQUV.⁴⁶

A comprehensive and large molecular study performed with OROV isolates focused on phylogenetic analysis, as well as on dispersal and evolutionary aspects (see Figs. 191D.1 and 191D.2).⁴¹ The conclusions of the study were that OROV emerged in the Brazilian Amazon approximately 223 years ago and that, based on N gene (S RNA) data,

the genotype I was the first genetic lineage to emerge and was responsible for the emergence of the other genetic lineages, as well as for virus dispersal in northern South America.⁴¹

DIFFERENTIAL DIAGNOSIS

Because of the nonspecific nature of the symptoms, a clinical diagnosis of ORO fever is difficult to make, and often the disease is mistaken for other febrile illnesses such as dengue fever, Zika virus infection, yellow fever, chikungunya, and malaria. In fact, malaria and dengue fever initially were suspected as the cause of numerous epidemics of ORO fever. Detailed clinical records combined with epidemiologic data can help establish a differential diagnosis, the certainty of which hinges on the absence of plasmodia in blood samples and the lack of laboratory evidence of dengue infection. Other viral and bacterial febrile diseases must be considered in the differential diagnosis. Accordingly, clinical and epidemiologic data and nonspecific tests will need to be taken into account, although establishing an accurate diagnosis requires specific tests.

Febrile forms of the disease accompanied by an exanthem need to be distinguished from other exanthematous febrile symptoms caused by dengue, measles, parvovirus B19 infection, infection with human herpesvirus type 6 or 5, enteroviral infections, and allergies to medication. A potential problem in differentiating ORO fever was observed in Peru after the emergence of a new orthobunyavirus named Iquitos virus (IQTV), a reassortant virus containing the S and L segments of OROV and the M segment of an unknown Simbu serogroup virus.¹ Clinically the febrile disease caused by IQTV is identical to ORO fever.¹ Finally, differentiating cases of aseptic meningitis associated with OROV infection from cases of aseptic meningitis associated with other causative agents requires a specific etiologic diagnosis.

TREATMENT

Because ORO fever has no specific treatment, management is symptomatic. Rest is important and should be continued for several days after disappearance of the initial acute manifestations because relapses are thought to occur more often in patients who prematurely resume regular activities, particularly strenuous activities. Aspirin or another antipyretic should be taken to lower the fever, and the use of ordinary analgesics is recommended for headache, myalgia, and arthralgia. However, certain reported patients whose headaches failed to respond to this treatment were treated with morphine derivatives. Also recommended are fruit juices or glucose solutions. Severely dehydrated patients may be treated with intravenous fluids.

PREVENTION AND CONTROL

The most effective way to prevent, avert, or curb the impact of epidemics of ORO fever is to combat its vector, *C. paraensis*. To be effective, vector control effort needs to focus on the midge's adult and larval forms. Given that *C. paraensis* is habitually active during the day, application of insecticides to its habitats by thermonebulization or ultra-low-volume aerosolization may help to reduce populations of adult biting midges. Because this *Culicoides* species is most active during the late afternoon hours,³⁴ ultra-low-volume spraying may be more effective during this period. However, carefully planned studies are needed to assess how to maximize the effectiveness of spraying by determining the type and concentration of insecticide to be used, the necessary volume of insecticide per treatment area, the size of the droplets, the frequency and timing of applications, and other factors. At the same time, making an effort to control the larvae by applying larvicides to corresponding habitats or, better yet, by conducting drives to eliminate or burn breeding sites such as rotting cocoa bean husks and the decomposing trunks of felled banana trees is essential.¹⁴ Obviously, the success of these measures will depend largely on community involvement. Providing proper community education is important. People can protect themselves by applying insect repellent directly to the skin. However, these types of products provide only temporary action, and they may be unaffordable to the poor.

No vaccine against ORO fever exists at this time. In light of the relatively benign nature of this viral disease, developing a general-purpose vaccine for at-risk populations living in areas where they are exposed to the disease is difficult to justify.

191E ■ Toscana Virus

Rémi N. Charrel • Xavier de Lamballerie

HISTORY

Toscana virus (TOSV) was discovered in 1971 in phlebotomines in Italy. Three strains were isolated from female *Phlebotomus perniciosus* collected in Monte Argentario (Grosseto Province, central Italy).⁸⁶⁻⁸⁸ The first evidence that TOSV was causing disease in humans was provided 14 years later.³⁶ Subsequent clinical and epidemiologic studies performed in Italy confirmed its role in aseptic acute meningitis.^{14,15} Then studies from other Mediterranean countries confirmed the medical importance of TOSV as one of the major causes of aseptic acute meningitis and encephalitis during the summer in regions where phlebotomine vectors are present.^{50,60,71,76} A bibliographic search using “Toscana virus” as key words in the PubMed database retrieved 273 research and review articles, of which less than 30% reported clinical cases of infection in southern Europe and the islands of the Mediterranean.^{26,42,74} More recently, TOSV was isolated in northern Africa, thus demonstrating its presence on the southern shore of the Mediterranean.^{3,13} Despite increasing evidence of its major role in human disease, TOSV remains poorly studied, and most physicians have little awareness of its potential to cause central nervous system (CNS) infections.

ETIOLOGIC AGENT

Phleboviruses are arthropod-borne viruses that contain a negative-sense, single-stranded RNA genome that consists of three segments, designated large, medium, and small, that encode the RNA-dependent RNA polymerase,⁴⁰ the envelope glycoproteins, and the nucleoprotein, respectively. Phylogenetic analyses performed using the medium segment identified three major lineages separate from Rift Valley fever virus and Uukuniemi virus. Given that cross-reactivity among phleboviruses when using serologic techniques is not uncommon, the identification of these viruses has increasingly involved incorporating genetic approaches to characterize these virus isolates. According to the ninth report of the International Committee on Taxonomy of Viruses, TOSV is a serotype of the species *Sandfly fever Naples virus* within the genus *Phlebovirus* in the Bunyaviridae family.⁷² Serologic cross-reactions are observed among the viruses included in the Sandfly fever Naples virus antigenic group by using indirect immunofluorescence assay (indirect IFA), hemagglutination inhibition, complement fixation, or enzyme-linked immunosorbent assay (ELISA), thus distinguishing TOSV antibody from antibody directed to Naples, Tehran, Massilia, Punique, Granada, Zerdali viruses is not possible.^{22,24,91} Therefore studies based on ELISA or IFA techniques must be interpreted carefully because of possible misinterpretations as a result of antigenic cross-reactivity among distinct viruses. Only neutralization assays can discriminate viruses that belong to the same antigenic complex or species.

EPIDEMIOLOGY

Sandfly-borne phleboviruses have been isolated from phlebotomines in southern Europe, Africa, central Asia, and the Americas. Data indicate

that the same may apply to TOSV and *P. perniciosus* (or *Phlebotomus perfiliewi*). Until recently *P. perniciosus* and *P. perfiliewi* were the only recognized vectors of TOSV. Evidence if TOSV in regions where these two species are either absent or rarely found suggests that other species of phlebotomines that belong to the *Larrousius* subgenus are possible vectors (*P. ariasi*, *P. neglectus*, *P. tobbi*). The geographic distribution of TOSV covers southern Europe and northern Africa, the Balkans, and Turkey (Fig. 191E.1); additional studies are needed to assess whether it expands beyond this area.^{35,39,50,57,71}

Italy

Preliminary clues pointing to the role of TOSV in CNS infections in Italy were provided by case reports of imported cases diagnosed in the United States^{18,36} and Germany.⁸⁰ A large study carried out between 1977 and 1988 showed that the virus was the cause of meningitis in two different regions of Italy, Tuscany and Marche, with a seasonal peak occurring in August, corresponding to the peak of sandfly activity.⁶³ Striking evidence that TOSV was the most prominent viral cause of summertime meningitis was reported in the late 1990s.^{81,84} A study of children living in rural or suburban areas of Siena (central Italy) showed that 40% of meningitis or encephalitis cases could be linked to infection with TOSV.¹⁵ A 7-year study (1990–96) performed in Siena showed that 52% of aseptic meningitis cases in adults were associated with TOSV.¹⁴ All studies are in agreement regarding the monthly distribution of human cases of TOSV infections—the highest risk for acquiring TOSV is in August, then July and September, and finally June and October. Many reports describe TOSV cases in other regions of Italy, such as northern Italy, Emilia Romagna, Naples, Sicily, and Sardinia.^{19,25,32,48,54,55,66,73,85,89} Seroprevalence studies report rates that vary between 9% and 25%, indicating different levels of exposure according to regional and local environmental conditions; however, most of these serologic studies are based on ELISA or indirect IFA and should be considered with caution because of cross-reactions with other phleboviruses related with TOSV. The same comment applies to other countries but is not repeated, to avoid redundancy.

Spain

The first case of TOSV infection reported from Spain occurred in the late 1980s in a Swedish tourist after visiting Catalonia and was documented by plaque reduction neutralization test.³⁷ Subsequently, Spanish researchers and physicians reported many cases of TOSV infection and conducted several comprehensive epidemiologic studies demonstrating that TOSV was a major cause of meningitis in Spain.⁶⁰ A total of 15 strains of TOSV were isolated between 1988 and 1996 from the cerebrospinal fluid (CSF) of patients with acute aseptic meningitis in Granada, Spain.⁵⁷ A total of 724 CSF samples from patients with suspected aseptic meningitis were tested through viral isolation in cell culture. TOSV was isolated from the CSF of 17 patients (7% of all viral isolates), 15 of whom were previously reported in the foregoing reference. TOSV was ranked as the third most common cause of aseptic meningitis after

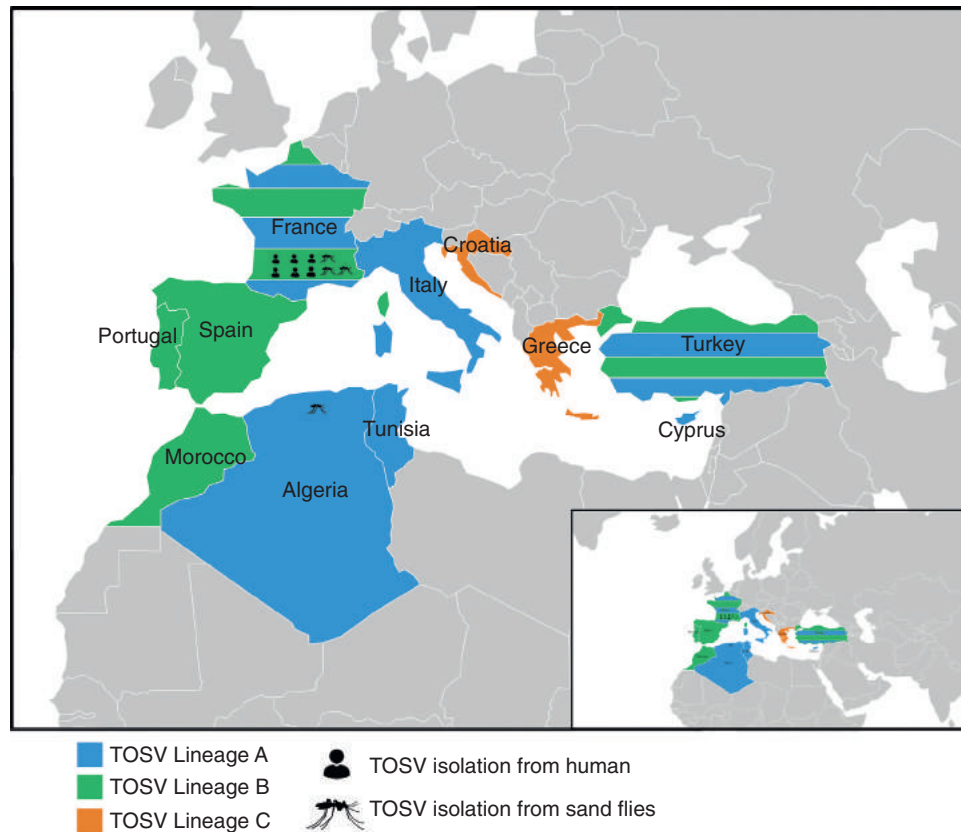

FIG. 191E.1 Geographic distribution of Toscana virus (TOSV) in the Mediterranean Area.

enteroviruses and mumps virus, a finding suggesting that its etiologic role in CNS infections in Spain is not as high as observed in central Italy. These data suggest that the situation in Spain is similar to that observed in France, with lower prevalence of CNS infections in contrast to those observed in central Italy. The testing of clinical samples with these assays confirmed the role of TOSV as a causative agent of acute aseptic meningitis in the central region of Spain.⁷⁵ In a collection of 88 serum and 53 CSF samples taken from 81 patients with acute aseptic meningitis of unknown origin who were living in Madrid or on the southern Mediterranean coast of Spain, seven patients were found to have acute TOSV infection (3 residents from the Mediterranean region and four from the Madrid region).³⁵ A large study conducted in different regions of Spain showed the presence of immunoglobulin (Ig) G antibodies to TOSV (26.2%), and Sandfly fever Naples virus (2.2%) in 1181 adults and 87 children.⁵⁷ A total of 457 serum samples taken from healthy persons, 2 to 60 years of age, from the south of the Madrid region was investigated for anti-TOSV IgG. The overall prevalence of anti-TOSV was 5%.³⁵

In the Granada region, the overall seroprevalence rate was 24.9%. A statistically significant increase in the seroprevalence rate was observed with age (9.4% in persons younger than 15 years in contrast to 60.4% in persons older than 65 years). In addition, several cases of TOSV infection were documented in numerous geographic areas of Spain (Badajoz, Málaga, Granada, Almería, Murcia, Alicante, Valencia, Madrid, and Barcelona), mostly in the southern, central, and Mediterranean areas of the country (EVITAR network, A. Tenorio, personal communication, 2003).

France

The first reported case of TOSV infection acquired in France was in a German traveler returning from southern France.³³ Five of 205 CSF samples retrospectively tested for TOSV RNA were positive, and they corresponded to patients living in the city of Marseille in southeastern France with no history of travel abroad. Sequence analysis indicated that these strains were most closely related to TOSV circulating in Italy.²¹ A total of 13 of 72 serum samples collected from April to September of 2003 in patients admitted for meningitis contained specific

IgM by using an ELISA test.²⁸ Twelve percent ($n = 11$) of 92 healthy blood donors from Marseille tested positive for specific IgG.²⁸ Similar prevalence rates were reported later.¹⁶

During the national surveillance for West Nile virus in southern France, many cases of acute TOSV infections were diagnosed by the National Reference center for Arboviruses and the virology laboratory of the Public Hospitals of Marseille.^{34,58,64} Together these findings indicate that strains of TOSV belonging to both the Italian and Spanish genotypes are co-circulating in the region, and both cause human infections.^{9,21,50,71}

Together, these data confirm that TOSV circulates in southwestern and southeastern France, as well as in Corsica island,^{12,27} and it ranks third as an etiologic agent of aseptic meningitis.

Cyprus

Several studies were conducted in Swedish United Nations soldiers based in Cyprus in 1985. Blood samples were obtained from the 362-soldier battalion just before and immediately after their 6-month tour of duty. Of 298 serum pairs available, seroconversion for TOSV was observed in a single case without any clinical manifestations.³⁹ Seroprevalence studies showed that 20% (96 of 479) of the healthy population of the island had TOSV IgG.³⁸

Greece

Studies of populations living on two Ionian Islands and in northern Greece showed a seroprevalence of 11% and 48%, respectively.^{5,68}

The first direct evidence for the presence of TOSV in Greece was described in 2014 with a case of encephalitis caused by a strain belonging to the lineage C (also reported in Croatia).⁶⁷ Seroprevalence studies (using IFA) demonstrated that TOSV and antigenically related viruses were actively circulating in the islands of Aegean Sea, in northern Greece and in the Ionian islands.^{5,6,68}

Portugal

One imported case of TOSV was reported in Portugal, in a man who presented with severe headache and fever without neck stiffness. Viral

isolation was successful, and identification was performed by plaque neutralization.³⁶ In addition, a German patient returning from vacation in Portugal developed meningitis; the diagnosis was established by ELISA and confirmed by immunoblot assay.⁷⁹

A seroepidemiologic study, performed with IFA and ELISA, showed that TOSV IgG was found in 2% of blood donors ($n = 150$), in 1.3% of sera from symptomatic persons with a laboratory diagnostic request for vector-borne viruses without neurologic signs, and in 4.2% of serum samples from symptomatic persons with a laboratory diagnostic request for vector-borne viruses with neurologic signs. Interestingly, only five of 29 serum samples that tested positive through IFA or ELISA were confirmed to be positive by plaque reduction neutralization assay with the Italian strain of TOSV. This finding suggests that phleboviruses other than TOSV may circulate in Portugal and infect human populations.⁴

In the north of Portugal, of 106 CSF samples collected between May and September from 2002 to 2005 in patients younger than 30 years who were tested for TOSV RNA, six tested positive, and all had a benign course and self-limited disease.⁷⁶

North Africa (Tunisia, Algeria, and Morocco)

Several studies suggest that TOSV circulates in the countries located on the southern shore of the Mediterranean Sea. Present data consist of serologic studies,⁸ which are prone to cross-reaction that may confuse TOSV with genetically related phleboviruses that have been recently discovered.^{59,91} TOSV has been detected or isolated from sandflies collected in Morocco^{45,46} and in Tunisia.¹³ Human infection has been demonstrated in Tunisia and in Algeria, and the results suggest that TOSV may have a much greater impact there than in Europe.^{2,47}

Turkey

TOSV is present in Turkey, where it causes human infections.^{42,44} Human cases were described in Aegean Turkey, in eastern Thrace, and in central Anatolia. Molecular evidence indicates that strains belonging to the lineages A and B are present in Turkey.^{30,41,42,65} To date, lineage A TOSV RNA has been described in phlebotomies in dogs and in humans, whereas lineage B TOSV RNA has been reported in dogs only.³⁰ A comprehensive review is available for details of TOSV in Turkey.⁴³

Other Countries

TOSV neutralizing antibodies were detected in humans populations living in Djibouti (East Africa).⁷ Patients presenting with neurologic manifestations or with fever of unknown origin should be tested for TOSV using polymerase chain reaction (PCR) assay or cell culture to assess the medical importance suggested by serologic findings.

CYCLE IN NATURE

Vectors of Toscana Virus

TOSV was isolated first from *P. perniciosus*. Other strains have been isolated from *P. perfliewi* but never from *P. papatasi*. TOSV also has been isolated from the brains of the bat *Pipistrellus kuhlii* trapped in areas where *P. perniciosus* and *P. perfliewi* were present.^{86–88} Isolation from bats has been reported for a large number of mosquito-borne arboviruses, including flaviviruses such as yellow fever virus, dengue virus, West Nile virus, and St. Louis encephalitis virus, with no clear information on implications for the ecologic cycle of these viruses. Transovarial transmission of TOSV in sandflies has been demonstrated in the laboratory and by viral isolation from male *Phlebotomus* species. Venereal transmission from infected males to uninfected females also has been demonstrated. *P. perniciosus* is distributed throughout the Mediterranean region as two races. The typical *P. perniciosus* race occurs in Italy, as well as in Malta, Tunisia, and Morocco. It is replaced in southern Spain by the Iberian race (with the pni mitochondrial DNA sublineage).⁷⁰ TOSV was detected in both male and female pools of phlebotomine sandflies captured during the summer seasons of 2003 and 2004 in Granada. The most probable transmission vector for TOSV in Spain is *P. perniciosus*, because approximately 70% of captured individuals corresponded to this species. Detection in pools of males suggests vertical or sexual transmission of TOSV among sandflies. TOSV

RNA was detected once in *Sergentomyia minuta*; additional studies are needed to confirm this finding and to assess the potential role of this species in the cycle of TOSV. Results showing a much larger distribution of TOSV (North Africa, Balkans, Turkey) raise the question whether phlebotomines other than *P. perniciosus* and *P. perfliewi* can also transmit TOSV to vertebrates.

Reservoir of Toscana Virus

The nature of the reservoir remains highly controversial. TOSV has been isolated from the blood of humans, dogs, and the *Pipistrellus kuhlii* bat.⁸⁸ Transient and low viremia occurs after TOSV infection in humans.^{11,82} A large quantity of virus must be ingested to infect sandflies.²³ One study investigated domestic animals (i.e., horses, goats, pigs, cats, dogs, sheep, and cows) and found high seroprevalence rates in cats (60%) and dogs (48%), although no virus could be isolated, and TOSV RNA was detected in one goat only.⁶¹

CLINICAL MANIFESTATIONS

Asymptomatic or Minimally Symptomatic Infection

Seroprevalence studies suggest that some infections caused by TOSV are asymptomatic or minimally symptomatic. Additional studies will be necessary to evaluate the ratio of symptomatic to asymptomatic or minimally symptomatic infections.

Febrile Illness

In some cases, TOSV infection causes a self-limiting febrile illness without CNS manifestations. These patients usually are neither hospitalized nor investigated further and may account for the probable underestimation of TOSV infection rates. The proportion of this clinical form is unknown because of the lack of systematic documentation of fever of unknown origin in regions where TOSV is present.

Meningitis

After an incubation period ranging from a few days to a maximum of 2 weeks, the onset of disease is brutal (70%), with headache (100%, 1–5 days), fever (76–97%), nausea and vomiting (67–88%), photophobia (86%), malaise (62%), and myalgias (18%). On physical examination, stiff neck (53–95%), Kernig signs (87%), encephalitis (44%), focal neurologic defect (21%), seizures (12%), poor levels of consciousness (12%), paresis (1.7%), and nystagmus (5.2%) are apparent.^{34,52,63,89} In most cases reported thus far, CSF samples have contained more than 5 to 10 cells, with normal levels of glucose and protein. Leukocytosis (29%) or leukopenia (6%) may be observed in the blood. The mean duration of the disease is 7 days, and the outcome usually is favorable.^{34,56,64}

Other Central Nervous System Manifestations

Although TOSV infection in most cases is a mild disease with a favorable outcome, a few severe cases have been reported in the literature. Meningoencephalitis and pure encephalitis are not so infrequent, as shown in several series.^{10,25,31,34,52,56} One case of meningitis complicated by abducens nerve palsy was reported in a German tourist returning from Italy.⁷⁷

Other Disease Manifestations Not Involving the Central Nervous System

Other manifestations should also be considered during the warm season, such as myositis and fasciitis.⁵⁸

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

For diagnosis of suspected cases of TOSV, it is important to follow the clinical criteria and laboratory tests as recommended for the detection of arboviral infections.²⁰ A clinically compatible case of TOSV infection is defined as follows:

- Fever ($\geq 38^{\circ}\text{C}$ [$\geq 100.4^{\circ}\text{F}$]) as reported by the patient or a health care provider, and absence of neuroinvasive disease, or
- Fever ($\geq 38^{\circ}\text{C}$ [$\geq 100.4^{\circ}\text{F}$]) as reported by the patient or a health care provider, and

- Meningitis, encephalitis, acute flaccid paralysis, or other acute signs of central or peripheral neurologic dysfunction, as documented by a physician, *and*
- Absence of a more likely clinical explanation.

The laboratory tests necessary for virologic documentation are as follows:

1. *For confirmed cases:* A case that meets the foregoing clinical criteria and one or more of the following laboratory criteria for a confirmed case:
 - Isolation of virus from, or demonstration of specific viral antigen or nucleic acid in, tissue, blood, CSF, or other body fluid, *or*
 - Fourfold or greater change in virus-specific quantitative antibody titers in paired sera, *or*
 - Virus-specific IgM antibodies in serum with confirmatory virus-specific neutralizing antibodies in the same or a later specimen, *or*
 - Virus-specific IgM antibodies in CSF and a negative result for other IgM antibodies in CSF for arboviruses endemic to the region where exposure occurred.
2. *For probable cases:* A case that meets the foregoing clinical criteria for neuroinvasive disease and the following laboratory criteria:
 - Virus-specific IgM antibodies in CSF or serum but with no other testing.

Serology

Techniques such as indirect IFA, ELISA, complement fixation, and hemagglutination inhibition are broadly reactive (i.e., they can identify antibodies against virus strains within the Sandfly fever Naples antigenic complex). However, they cannot discriminate among the different strains. In other words, these techniques can hardly distinguish antibodies elicited by virus belonging to this serocomplex: TOSV versus other viruses such as Naples virus, another demonstrated human pathogen, but also Tehran, Massilia, Punique, Granada, Zerdali. Although some of these viruses are not demonstrated human pathogens, most of them can infect vertebrates; because sympatric distribution of several of these viruses is established (Massilia and TOSV, Punique and TOSV, Naples and TOSV), serologic cross-reactions can overestimate the prevalence of TOSV.^{22,91}

Immunofluorescence Assay

Seroconversion and the detection of IgG or IgM can be achieved in cells infected with TOSV. Apart from homemade assays, Euroimmun AG (Lübeck) is commercializing a mosaic test that incorporate TOSV, Naples, Sandfly fever Sicilian virus, and Cyprus virus. This assay can more or less easily discriminate between Naples and TOSV antibodies and between Sicilian and Cyprus antibodies.

Enzyme-Linked Immunosorbent Assay

ELISA tests have been developed with crude antigens, purified virus, or recombinant nucleoprotein. One ELISA test detecting IgG and IgM is commercially available (DIESSE Diagnostica Senese).^{35,57}

Rapid Immunochromatographic Test

An immunochromatographic assay has been developed for human anti-TOSV IgG or IgM detection, with performance similar to that observed with the commercial ELISA test.⁵¹

Neutralization Test

Techniques detecting neutralizing antibodies (plaque reduction neutralization test, virus neutralization test, microneutralization) are the tests of choice for definitive identification or confirmation of the results observed with broadly reactive assays. Although seroconversion remains the serology gold standard for establishing the diagnosis of viral diseases, the presence of specific IgM in a single serum sample is indicative of a recent infection.

Viral Isolation

Isolation from clinical samples can be achieved by using CSF or serum. TOSV replicates in a variety of animals; intracerebral, intraperitoneal, and subcutaneous routes lead to death in the newborn mouse;

intracerebral and intraperitoneal routes lead to death in the weanling mouse; in the guinea pig and rabbit, intracerebral inoculation results in paralysis and irregular death, whereas intraperitoneal inoculation is not fatal and results in antibody synthesis. *Macaca fascicularis* succumbs after intracerebral inoculation but recovers with antibody production after intraperitoneal inoculation.⁵³ TOSV replicates in Vero, BHK-21, CV-1, and SW13 cells with cytopathic effect but not in C6/36 cells.^{53,86}

Genome Amplification by Reverse Transcriptase Polymerase Chain Reaction Assays

Molecular diagnosis of TOSV can be achieved using three different real-time reverse transcriptase PCR assays that can be used to detect viral RNA in either CSF or serum of suspect cases.^{17,69,90} Over time, this technology has progressively supplanted classic PCR and nested PCR assays.^{75,78,83}

GENETIC DIVERSITY OF TOSCANA VIRUS

TOSV has been isolated from sandflies of two different species, *P. perniciosus* and *P. perfliewi*; from humans; and once from a bat (*P. kuhlii*). Viral TOSV RNA was detected in dog sera, but no virus isolation was obtained.^{30,92} The prototype TOSV strain, ISS Phl.3, isolated from *P. perniciosus* in 1971, has been sequenced completely and is used as reference for further genetic studies.^{1,29,49}

Many strains from Italy have been partially sequenced, and only minor differences in nucleoprotein sequences were found among strains isolated in the early 1980s from both species of sandflies, from the bat, and from humans, with no more than one amino acid substitution.⁶² Studies conducted with partial sequences in the polymerase gene indicate that a distinct genotype of TOSV is present in Spain.⁷⁵ This finding suggests the presence of at least two topotypes of TOSV, commonly designated lineage A and lineage B. Interestingly, strains from both lineages are co-circulating only in France and in Turkey.³⁰ A third lineage (lineage C) was identified in Croatia and in Greece.^{67,74} Distribution of the topotypes or lineages is presented in Fig. 191E.1.

Human Retroviruses

192A ■ Oncoviruses (Human T-Cell Lymphotropic Viruses) and Lentiviruses (Human Immunodeficiency Virus Type 2)

Michael A. Tolle • Susan L. Gillespie

In the 1980s retroviral infections were identified to be the cause of significant disease in humans, namely, human immunodeficiency virus (HIV) and human T-lymphotropic virus (HTLV) infections. Since that time, approximately 78 million people have been infected with HIV and 10 to 15 million with HTLV. Human retroviruses have a zoonotic origin. It is now well established that HIV and HTLV originated from simian retroviruses in nonhuman primates (NHPs) that crossed the species barrier to humans on several occasions, leading to the HIV and HTLV epidemics.⁴¹⁸

The discovery of human T-cell lymphotropic virus type 1 (HTLV-1) in 1980 demonstrated for the first time that humans could be infected by retroviruses, which previously were known as animal pathogens that could cause malignant disease.⁴²⁶ HTLV-1 subsequently was found to cause adult T-cell leukemia/lymphoma (ATLL) and now is recognized to be associated with the following spectrum of disease manifestations: a chronic degenerative neurologic disease (HTLV-1-associated myelopathy [HAM]/tropical spastic paraparesis [TSP]); relapsing, severe generalized dermatitis in children (infective dermatitis); and numerous inflammatory or autoimmune conditions, or both, such as uveitis, arthropathy, polymyositis, bronchoalveolitis, and Sjögren syndrome.⁴⁴⁰ In 1982, a second antigenically related retrovirus of the oncovirus subfamily, HTLV-2, was identified from a patient with a T-cell variant of hairy cell leukemia.²⁵⁰ The pathogenicity of this virus has become more clear over the years, being associated with other lymphoproliferative diseases and neuromyopathies, including diseases similar to HAM/TSP.^{52,86,458,487} The subsequent discovery of HTLV-3 and HTLV-4 demonstrated that diversity among these viruses is greater than previously understood.

HIV-1 was identified as the cause of acquired immunodeficiency syndrome (AIDS) in 1983. HIV-2, a related but antigenically distinct virus, was isolated for the first time in 1986 from two West African patients.¹⁰¹ HIV-1 and HIV-2 are lentiviruses.

CLASSIFICATION

Retroviruses form a large and diverse family of single-stranded RNA viruses that are unusual because they contain a diploid RNA genome

that replicates by flow of genetic information through a DNA intermediate, a process known as reverse transcription. The name retrovirus is derived from this characteristic. This unique capability results from the presence of a virally encoded RNA-dependent DNA polymerase, reverse transcriptase, which catalyzes transcription of viral RNA into a double-stranded DNA copy. This viral DNA intermediary becomes integrated into host-cell DNA, where it then resides as a provirus; this process occurs by a specialized recombination mechanism requiring another viral protein, integrase. This capacity for genomic integration correlates with the capability of retroviruses to cause lifelong infection, evade the usual mechanisms of immune clearance, and produce chronic diseases in the host that manifest only after a long asymptomatic period that may last years to decades. Retroviruses infect both animals and humans.

Retroviruses can be categorized as being either exogenous or endogenous. Exogenous retroviruses such as HIV and HTLV are transmitted between individuals and across species, whereas endogenous retroviruses have become part of the genetic material of their host species through the chromosomal integration of viral DNA in the host germ cells, which then allows for vertical transmission of viral genetic material and fixation in the host population. Through whole-genome sequencing, it is estimated that 1% of the human genome consists of human endogenous retrovirus sequences resulting from infections millions of years ago.

The classification of retroviruses has been complicated by the ongoing discovery of new viruses and elucidation of their genetic organization and replication. At one time, retroviruses were divided historically into three subfamilies on the basis of nucleotide sequences and genetic organization. The subfamilies were the Oncovirinae (oncogenic or transforming viruses, which include HTLV), the Lentivirinae (slow viruses with cytopathic effects, which include human immunodeficiency virus types 1 [HIV-1] and 2 [HIV-2]), and the Spumavirinae (foamy viruses). Retroviruses have been also classified according to morphologic and biologic criteria based on the observance of retroviral particles in infected cells. Currently, human retroviruses have been broadly classified into five groups, three of which include only endogenous viruses

FIG. 192A.1 Retroviral structure. The mature retroviral virion is spherical; the central viral core is spherical in human T-cell lymphotropic virus oncoviruses and cylindric in human immunodeficiency virus lentiviruses. The core is surrounded by a lipid bilayer envelope derived from the host-cell membrane during budding, the surface projections consisting of the viral surface and transmembrane envelope proteins. The viral matrix surrounds the virion core and is associated with the viral transmembrane envelope glycoproteins. The virion core is a structural shell composed of the viral capsid proteins. Within the shell are two copies of single-stranded viral RNA and multiple copies of the virally encoded reverse transcriptase, protease, and integrase enzymes. The viral nucleocapsid protein is bound to the RNA copies and may serve to condense the viral RNA into the capsid shell during virion assembly.

(betaretroviruses, spumaviruses, and gammaretroviruses) and two groups for exogenous viruses (lentiviruses [e.g., HIV] and deltaretroviruses [e.g., HTLV]).

Morphology and Genomic Structure

Retroviruses have a distinct morphology. They are enveloped RNA viruses that have a diameter of 80 to 120 nm; a thin, electron-dense outer envelope; and an electron-dense core that is either spherical (HTLV) or cylindrical (HIV). The envelope of all retroviruses comprises a lipid bilayer derived from the host-cell plasma membrane during budding of the virus from the cell surface, with surface projections consisting of the viral envelope proteins (Fig. 192A.1). The retroviral core protein encloses a ribonucleoprotein of genomic RNA complexed with viral reverse transcriptase and integrase.¹⁰² The genome is a messenger-sense, linear, single-stranded RNA comprising two identical subunits held together by hydrogen bonds at their 5' ends. The 5' and 3' ends of the RNA contain repeated sequences that give rise to elements in viral DNA called *long terminal repeats* (LTRs).

The LTRs are composed of nucleic acid sequences that provide signals critical for structural transformation of the viral genome, including initiation and progression of reverse transcription of viral RNA into DNA, integration of viral DNA into the host genome by viral integrase, and initiation of viral messenger RNA (mRNA) transcription from the integrated provirus and binding sites for viral and cellular proteins, and that positively and negatively influence mRNA transcription.^{445,515,541,581} Between the LTRs are the genes that encode the major structural proteins of the virus, the enzymes found in the viral particles, and additional proteins with specialized intracellular functions.

As noted earlier, all retroviruses contain a minimum of three genes: *gag*, *pol*, and *env*. They are arranged in a 5' to 3' order, with LTRs at each end (Fig. 192A.2). The *gag* gene encodes the structural protein products that form the core particle of the virus, including nucleocapsid, capsid, and matrix proteins. The *pol* gene products include the enzymes

required for genome replication (viral RNA-dependent DNA polymerase and ribonuclease H), proviral integration (integrase), and polyprotein processing (protease). The *env* gene encodes the major components of the viral coat, the surface, and transmembrane glycoproteins. Retroviral genes generally are expressed first as large, overlapping polypeptides that undergo processing into functional peptide products by viral or cellular proteases.

Oncoviral Regulatory and Accessory Genes

In addition to the standard retroviral genes, the oncoviruses HTLV-1 and HTLV-2 contain several regulatory and accessory genes important for viral replication and activation of host genes that are encoded in open reading frames (ORFs) in a unique region at the 3' end of the genome called the pX region.^{5,230} The HTLV-1 pX region contains four ORFs, whereas HTLV-2 contains five ORFs. Two of these ORFs common to both viruses (ORF III and ORF IV) encode the regulatory proteins Rex and Tax.

The regulator of expression of virion proteins gene (*rex*) encodes a nucleolus-localizing phosphoprotein that affects mRNA splicing and export from the nucleus to the cytoplasm. For cellular genes, mRNA splicing and export are tightly coupled. After cellular genes are transcribed into mRNA, splicing occurs in the cell nucleus before mRNA can be exported into the cytoplasm for translation into proteins. Incompletely spliced mRNA molecules are retained in the nucleus.^{343,344,515} However, for retroviral reproduction, the export of full-length, unspliced viral RNA into the cytoplasm is required to serve as genomic RNA for integration into progeny virions and mRNA for the production of viral structural proteins. Thus retroviruses had to develop a mechanism to bypass the cellular regulatory process; for HTLV, the Rex protein serves this function. This protein is expressed predominantly at an early stage of viral gene expression and enhances the transport of single-spliced and unspliced viral mRNA coding for structural proteins, as well as transport of the viral genome from the nucleus to the cytoplasm. The Rex protein also

FIG. 192A.2 Retroviral genome. This schematic depiction of the human T-cell lymphotropic virus (HTLV) and human immunodeficiency virus (HIV) genomes shows that HTLV has a more complex genome than most animal retroviruses do and that HIV, in turn, has additional regulatory genes. Details of the functions of these genes are summarized in the text. *LTR*, Long terminal repeat. (From Gallo RC, Wong-Staal F, Montagnier L, et al. HIV/HTLV gene nomenclature. *Nature*. 1988;333:504.)

exerts a negative effect on the transport of multiply spliced viral mRNA to the cytoplasm. These multiply spliced mRNA molecules code for regulatory proteins, including Rex and Tax.⁵⁴¹

The transactivator gene (*tax*) encodes a nuclear protein that plays a critical role in the regulation of viral replication and also stimulates a large number of cellular genes involved in activation and proliferation of T cells, including lymphokines, lymphokine receptors, and nuclear protooncogenes.^{595,596} The Tax protein does not bind directly to DNA but rather interacts with host-cell transcriptional factors to produce a multifaceted array of molecular effects.⁴⁶ The Tax protein activates mRNA transcription by binding to several different host-cell transcription-enhancing factors, including those of the nuclear factor (NF)- κ B family. In addition to activating transcription of the HTLV genome, the Tax transcription factor complex stimulates transcription of many cellular genes, including those encoding interleukin-2 (IL-2), IL-2 receptor- α , tumor necrosis factor (TNF), cyclooxygenase 2 (a prostaglandin synthetase), and some nuclear oncogenes.^{358,595,596} Tax also represses transcription of tumor suppression genes and the expression of cellular DNA polymerase- β , a key enzyme for repair of damaged DNA. Additionally, Tax can bind directly to and inhibit some cell cycle regulation and tumor suppressor proteins, thereby interfering with cell cycle regulation and resulting in abnormal promotion of the cell cycle and enhancement of cellular proliferation.⁵⁹⁶ Finally, Tax increases the genetic instability of the cell by impairing cellular DNA repair mechanisms, a process that leads to an accumulation of mutations and an increase in chromosomal anomalies. In vitro, Tax protein can immortalize human T cells and induce tumors in transgenic mice. However, in vivo, malignant disease develops in fewer than 5% of HTLV-1-infected individuals. Thus, although the *tax* gene probably is involved in malignant transformation of infected T cells, this is not sufficient by itself to explain the final development of malignancy.^{7,546,595,596}

Less is known about the function of the HTLV accessory proteins that are encoded by the remaining ORFs in the pX region (e.g., p12, p13, and p30 in HTLV-1; p10, p11, p22/20, and p28 in HTLV-2). The best characterized accessory protein is HTLV-1 p12 from ORF I, which is a conserved, hydrophobic protein localized to the internal cell plasma membrane and perinuclear regions of the cell.⁹² The p12 protein contains amino acid motifs commonly found in proteins involved in intracellular signaling pathways and probably interacts with cellular proteins, perhaps cellular kinases, to modulate intracellular signaling in infected cells. The protein also interacts with the β and γ chains of the IL-2 receptor. This protein may be required for activation of host cells during the early stages of infection, for cellular transformation, and for efficient

viral infectivity, similar to the function of the *nef* gene of the lentivirus HIV-1.³ The corresponding ORF I protein in HTLV-2, p10, does not bind the IL-2 receptor and is not associated with the constitutive activation of the IL-2 signaling pathway that is seen with HTLV-1-transformed cells.⁹² These differences may be associated with differences in pathogenicity between the two oncoviruses.

Lentiviral Regulatory and Accessory Genes

More detailed data are available on the function of lentiviral genes.¹⁴⁴ The lentiviruses HIV-1 and HIV-2 have more complex genomes containing at least six regulatory genes in addition to *env*, *gag*, and *pol*. The lentiviral genes corresponding to the oncoviral *tax* and *rex* are called *tat* and *rev*; these genes are found in all known human and animal lentiviruses and appear to be essential for replication.^{343,344}

Like the oncoviral *rex* gene, *rev* is expressed early in the viral replication cycle and undergoes splicing in the nucleus; multiply spliced *rev* mRNA transcripts then are exported to produce Rev protein in the cytoplasm. This protein contains a nuclear localization signal that facilitates entry of the protein back into the nucleus. Rev then binds to unspliced viral mRNA at a *cis*-acting Rev response element (RRE) located on the mRNA. A nuclear export signal sequence on the carboxy-terminal domain of Rev next targets the unspliced viral mRNA for export to the cytoplasm by binding to the cellular protein CRM1 (exportin 1) and exiting the nucleus through the host-cell export pathway.¹⁰⁸ The full-length unspliced viral mRNA then serves as a translational template for expression of the Gag and Pol proteins and also serves as genomic RNA for incorporation into new virions.

In contrast to the oncoviral Tax protein, which binds to host-cell proteins and has multiple effects in addition to promoting initiation of HTLV gene transcription, the lentiviral Tat protein binds to an RNA target, the Tat activation region (TAR), located immediately 3' to the LTR transcription start site, and plays a primary role in the expression of HIV viral transcripts by enhancing mRNA elongation. At least two host-cell cofactors are involved in this process.⁵⁹⁹ Cellular cyclin T binds to the activation domain of Tat, which increases both the affinity and specificity of the resulting complex for TAR. A host-cell encoded kinase then is recruited to the Tat-cyclin T-TAR complex and phosphorylates the carboxyl-terminal domain of the host-cell RNA polymerase II, which in turn enhances mRNA transcript elongation.

The remaining lentiviral accessory regulatory genes *nef*, *vpr*, and *vif* provide fine-tuning by enhancing or, less commonly, by diminishing viral replication. Another accessory gene, *vpu*, is found only in HIV-1, whereas HIV-2 and simian immunodeficiency virus lack the *vpu* gene

but contain a gene called *vpx*. The *nef* gene, like *tat* and *rev*, is expressed early in the replication cycle. Similar to the HTLV-1 p12 protein, *nef* encodes a hydrophobic, membrane-associated protein that probably interacts with and modulates cellular signaling pathways and is required for optimal infectivity in vivo and for activation of infected host cells. Nef protein significantly enhances the cytoplasmic delivery of viral particles entering the cell through fusion at the plasma membrane, possibly by enhancing phosphorylation of the viral matrix protein and thereby allowing dissociation of the matrix and associated preintegration nucleoprotein complex from the virion capsid proteins.^{170,515} Nef also downregulates cell surface expression of CD4⁺ by accelerating CD4⁺ receptor endocytosis through interaction with the cytoplasmic tail of CD4⁺ and a protein complex (i.e., AP-2 adaptor complex) responsible for recruiting membrane-associated proteins to clathrin-coated pits for endocytosis.¹⁴⁴ This process reduces the potential interference of membrane-associated CD4⁺ with the release of budding virions. Major histocompatibility complex (MHC) class I receptor expression also is downregulated by Nef.

The Vpr protein is present in the virion itself, may act to regulate cellular events after penetration and uncoating of the virus to facilitate viral replication, and is involved in efficient localization of the nucleoprotein preintegration complex into the nucleus.^{102,214} Vpr appears to interact with a specific site on nucleoporins in the nuclear pore complex to facilitate nuclear entry.⁵¹⁵ Similar to the Vpr protein, the HIV-2 Vpx protein is found in the virion and appears to affect the efficiency of early replication events, but the precise mechanism is unknown.^{102,290}

The virion infectivity factor (*vif*) accessory gene is expressed late, along with structural and enzymatic proteins. The Vif protein is predominantly cytoplasmic but also exists in a membrane-associated form.^{343,344} Vif protein is phosphorylated by a host-cell protein kinase, which seems to be important for viral growth in primary cells.²⁰¹ Vif appears to stabilize the preintegration provirus; viral particles that are produced in the absence of Vif are incapable of incorporating the provirus into host-cell chromosomes.^{343,344} Vif also may function to prevent premature processing of Gag precursor proteins by viral protease in the cytoplasm, thereby ensuring that the Gag-derived peptides that form the viral nucleoprotein core are available at the plasma membrane for assembly with other viral components.

The HIV-1 *vpu* gene also is expressed late. The Vpu protein is associated with the endoplasmic reticulum in infected cells, where it binds the CD4⁺ molecule and prevents it from translocating to the plasma membrane; instead, the CD4⁺ molecule is targeted for proteolysis through the cytoplasmic ubiquitin-proteasome pathway.^{144,515} This process prevents trapping and subsequent degradation of HIV envelope proteins by CD4⁺ in the cytoplasm, thus increasing the ability of the viral envelope proteins to reach the cell membrane. Vpu, like Nef, also downregulates MHC class I receptor expression. In addition, Vpu may be important in virion assembly and release of particles.^{95,177,564}

Viral Replication

The lentiviruses can infect and replicate in nondividing, terminally differentiated cells, and transmission can occur by cell-free or cell-associated virus. HIV-1 has high replication rates in vivo, with an average of 10⁹ to 10¹⁰ viral particles produced each day. Free viral particles are estimated to have a half-life of less than 6 hours, and productively infected cells have a half-life of approximately 1 day.^{228,387,570} The relentless rounds of reverse transcription rapidly generate extensive viral genetic variation within a single individual that results in a genetically related “swarm,” or quasi-species, of viruses and provides the ability to escape the host immune response rapidly.

In contrast, the oncoviruses require that host cells undergo division for productive infection to be established, and they replicate in vivo largely by mitosis rather than by reverse transcription.³²⁰ In addition, transmission is predominantly, if not solely, accomplished by means of cell-to-cell contact.¹²⁶ The events that occur during primary HTLV infection are reverse transcription of the viral genome, integration of the provirus into DNA, transcription of mRNA, synthesis of viral proteins, and a burst of viral expression. However, after a period of active replication, viral persistence is facilitated by a prolonged phase of clonal proviral expansion produced by transactivation of host-cell genes by Tax, which

results in cellular DNA replication and the production of new cells containing the HTLV proviral genome.³⁶¹ Unlike viral nucleic acid replication by the error-prone viral reverse transcriptase, cellular mitosis is much less prone to mutation and generates little viral genetic variation. Moreover, the provirus remains hidden from immune surveillance. Thus oncoviruses have extraordinary genetic stability, in contrast to lentiviruses. The genetic variability of the HIV-1 envelope protein that exists within the viral quasi-species in a single individual 5 years after infection is greater than the genetic variability found in all HTLV-1 proteins identified worldwide to date.⁵⁶⁹

These differences are related to divergence among the retroviral subfamilies in genetic organization, transcription, and function of the major regulatory genes (*tax* and *rex* for the HTLVs and *tat* and *rev* for HIVs). The Tax and Tat proteins both are transactivating enhancer proteins. However, the HTLV Tax protein interacts with cellular proteins and activates cellular genes, thereby resulting in disruption of the cell cycle and induction of cell proliferation. In contrast, the HIV Tat protein has more focal effects; it recognizes a small RNA domain in the HIV LTR and serves primarily to transactivate HIV replication. The Rex and Rev proteins have similar functions; both interact with genomic mRNA structures (the Rex-responsive element and Rev-responsive element) to enhance transport of the unspliced and partly spliced viral mRNA molecules from the nucleus to the cytoplasm, and both also downregulate the transport of multiply spliced mRNA transcripts that encode for early regulatory proteins, including the mRNA molecules coding for themselves. In the oncoviruses, Tax and Rex are derived from the same mRNA; therefore downregulation of Rex mRNA transport results in decreased Tax mRNA transport and protein production. This process leads to diminished transactivation of HTLV genome transcription and prevents massive viral production. In contrast, the HIV Tat protein comes in two functionally equivalent forms, a 72- and an 86-residue protein. The 72-residue Tat protein is derived from a joint Rev/Tat mRNA, but the 86-residue Tat protein comes from a small Rev-independent mRNA. Although Rev, like Rex, has a negative effect on its own expression, as well as that of Tat, this effect is mitigated by the expression of a Tat mRNA that is not dependent on expression of Rev mRNA, thereby resulting in continued production of the Tat transactivating protein and constant and massive transcription of the HIV genome.

Retroviral Life Cycle

All retroviruses have two phases in their life cycle: an infection phase (including viral attachment, entry, reverse transcription, and proviral integration) and an expression phase (including transcription, translation, assembly, and budding of the virion) (Fig. 192A.3).¹⁰² In general, more detail is known about replication in lentiviruses than in oncoviruses.

Infection phase of retroviral replication. Retroviruses attach to cells through recognition and binding of viral outer surface envelope proteins to specific proteins on the surface of the host cell; such cell surface receptor specificity probably accounts for the species and cellular tropism of retroviruses.^{246,383} The surface glycoprotein of the retroviral envelope has three structural and functional domains separated by conserved hinges and is noncovalently linked to the transmembrane protein by disulfide bonds. The envelope transmembrane protein anchors the entire envelope glycoprotein complex on the virion surface and is responsible for the fusogenic capacity of the viral envelope. The transmembrane protein of all retroviruses has several conserved motifs, including a “leucine zipper” coiled motif followed by the N-terminal hydrophobic “fusion peptide” responsible for fusion with the host-cell membrane. After binding of the viral surface protein to the host-cell receptor occurs, conformational changes permit correct exposure of the transmembrane fusion peptide to the host-cell membrane. The interaction of several fusion peptides may serve to destabilize the lipid bilayer of the target-cell membrane by forming a “fusion pore” between the two bilayers⁸² to facilitate fusion of the viral and cellular membranes and release of the viral RNA–protein complex into the cytoplasm.^{198,500,546}

The cell surface receptor for HTLV-1 and HTLV-2 has not been characterized completely. Oncoviruses transmit infection primarily by fusion of infected cells with uninfected cells and the subsequent formation of syncytia. In HTLV-1, fusion is thought to be mediated by the HTLV envelope proteins expressed on the surface of infected cells and by cell

The HIV Life Cycle

HIV medicines in six drug classes stop HIV at different stages in the HIV life cycle.

FIG. 192A.3 Life cycle of retroviruses. Details of viral replication are discussed in the text. (From AIDSinfo: The HIV Life Cycle. <https://aidsinfo.nih.gov/education-materials/fact-sheets/19/73/the-hiv-life-cycle>. Last updated 9/13/16.)

adhesion molecules, such as vascular cell adhesion molecule type 1 (VCAM-1), intracellular adhesion molecule type 1 (ICAM-1), ICAM-3, and the membrane permease CD98, on target-cell surfaces.⁴⁶ Although HTLV-1 envelope-expressing infected cells can form syncytia with cells from most cell lines, in vivo, HTLV-1 is found only in CD4⁺ lymphocytes.¹²⁶ In contrast, HTLV-2 displays a preferential tropism for cells of the CD8⁺ T-lymphocyte phenotype.^{240,282}

The lentiviruses HIV-1 and HIV-2 infect cells that express CD4⁺, the human leukocyte antigen (HLA) class II receptor, on their cell surface.³⁸³ These cells include CD4⁺ T lymphocytes, cells of the monocyte and macrophage lineage, and microglia in the brain. A high-affinity interaction between the surface glycoprotein and the CD4⁺ receptor produces a conformational change that results in exposure of another site with high affinity for a secondary coreceptor required for the entry of HIV-1 and some HIV-2 isolates into the cell. The chemokine receptor CCR5 is the coreceptor used by monocyte-tropic and macrophage-tropic HIV-1, whereas the CXCR4 chemokine receptor is used by T-lymphocyte-tropic HIV-1; although most HIV-1 strains use only one receptor, some strains of HIV-1 are dually tropic and can use both receptors.¹²⁶ Additional coreceptors may support the entry of more restricted types of HIV isolates. For example, the chemokine receptor CCR3 is used by some macrophage-tropic HIV-1 strains and mediates entry of the virus into microglia; CCR2b, CR8, STLR/STRL-22, GPR15, GPR1, and the cytomegalovirus protein US28 also support entry by various HIV-1 and HIV-2 strains.^{206,515} Whereas nearly all strains of HIV-2 can use CD4⁺ together with the chemokine receptor CCR5 or CXCR4 (or both), most HIV-2 isolates also can interact with multiple other coreceptors.^{206,515} Additionally, some HIV-2 isolates can use CXCR4 or other receptors, such as CCR3, as a primary receptor and infect cells lacking the CD4⁺ molecule.¹⁴⁵

Early postentry events include uncoating of the virus, which appears to require interaction of viral structural proteins with host-cell components that may have been incorporated into the virion during viral assembly. In HIV-1, interaction of the viral capsid protein with the host-cell cyclophilin A that is associated with the virion core during viral assembly may destabilize the multimeric capsid complex.^{298,515} Additionally, a virion-associated host-cell protein kinase phosphorylates the viral matrix protein and thereby allows dissociation of the capsid and nucleocapsid proteins from the rest of the virus at the cell membrane. The HIV-1 Vif protein, which colocalizes with the Gag-derived proteins, is thought to confer enhanced stability to the remaining cytoplasmic viral nucleoprotein complex.

Retroviral RNA-to-DNA transcriptional events are initiated in the cytoplasm through the action of the viral enzymes reverse transcriptase (RNA-directed DNA polymerase) and ribonuclease. Viral single-stranded RNA is transcribed into a viral RNA/DNA hybrid complex by the DNA polymerase; the ribonuclease then destroys the original RNA and permits the DNA polymerase to complete transcription of a second DNA strand to form a linear double-stranded DNA copy of the original viral RNA.¹⁹⁸ Retroviral integration is mediated by a large nucleoprotein complex that forms in the cytoplasm and is called the preintegration complex. This complex includes the viral nucleic acids and a subset of viral proteins, including the matrix protein, reverse transcriptase, integrase, and, in the lentiviruses, Vpr.⁵¹⁵ The viral integrase enzyme component of this complex recognizes specific sequences within the viral LTR and cleaves two nucleotides from the 3' ends as an initial processing step for integration; this process occurs while the preintegration complex is still in the cytoplasm.¹⁹ Integrase appears to be the principal viral determinant of integration specificity.²⁹² In the lentiviruses, which can infect nondividing cells, the preintegration complex is imported actively into the nucleus during interphase. Nuclear transport is mediated by nuclear localization sequences on the matrix protein and on integrase and by interactions of Vpr with nucleoporins in the nuclear pore complex.

After nuclear entry has been gained, the integrase joins the recessed 3' ends to phosphates in the host DNA for insertion of the DNA duplex into the host genome.^{19,103} A final step in integration is thought to involve cellular factors that participate in DNA repair, in particular, a DNA-dependent protein kinase. This kinase is hypothesized to repair gaps left by the integrase around the sequence inserted into the host DNA; the result is a fully integrated provirus.¹¹¹

Expression phase of retroviral replication. After viral DNA is integrated into the host cell, the proviral genome resembles other cellular genes and becomes highly dependent on the host cell for further replication, with the host-cell machinery used for replication, expression, and production of protein. Regulation of transcription is a complex process requiring interaction among the integrated proviral LTRs, host-cell DNA transcription factors, and the lentiviral Tat protein or oncoviral Tax protein.

The early phase of viral gene expression is characterized by the presence of spliced and unspliced viral mRNA in the nucleus, but only multiply spliced mRNA in the cytoplasm. In HTLVs, these mRNA molecules serve to direct production of the Tax and Rex regulatory proteins; in HIVs, they direct production of the Tat, Rev, and Nef proteins. The transition from early regulatory to late structural gene expression is characterized by the selective transport of unspliced and partially spliced mRNA into the cytoplasm. As discussed previously, in lentiviruses, this process depends on sufficient amounts of the Rev protein and, in oncoviruses, the Rex protein.^{102,546} The unspliced or partially spliced mRNA transcripts that enter the cytoplasm encode for structural proteins and are first expressed as large, overlapping polypeptides. These polypeptides undergo processing into functional peptide viral structural components by the action of virally encoded and host-cell protease enzymes.

The retroviral Env protein is synthesized as a large precursor protein; it undergoes initial glycosylation in the endoplasmic reticulum, with subsequent disulfide bonding, folding, and oligomerization, and then is transported to the Golgi complex, where it is cleaved by a host-cell protease into surface and transmembrane proteins, which undergo further glycosylation.¹²⁶ The two mature glycoproteins are noncovalently associated through disulfide bonds. After cleavage occurs, the complexed proteins are transported and inserted into the plasma cell membrane by the cellular secretory pathway.^{158,159}

The retroviral *gag* and *pol* genes are transcribed into a single mRNA transcript, which subsequently is translated into two separate polypeptide precursors, the Gag and Gag-Pol precursor proteins; the Gag-Pol polypeptide is translated by a ribosomal frame shift between the Gag and Pol mRNA reading frames. The Pol component of the Gag-Pol precursor protein is cleaved to form the viral enzymes reverse transcriptase, ribonuclease, and protease. The Gag precursor encodes the major structural proteins of the virion core, which do not undergo proteolytic processing into mature proteins until after assembly of the immature virion at the plasma membrane occurs.

Virion assembly and budding occur through targeting, accumulation, and association of different domains of the Gag and Gag-Pol precursor proteins at the inner face of the plasma membrane where the envelope proteins are being expressed.^{158,159,562} The M domain, an amino acid sequence contained in the N-terminal area of the matrix portion of the Gag protein, has a membrane-targeting sequence that directs the Gag and Gag-Pol polypeptides to the cytoplasmic face of the plasma membrane. Myristylation of the N-terminal portion of some (lentiviruses) or all (oncoviruses) of the Gag precursor protein matrix domain is required for membrane targeting to occur and to allow Gag protein assembly at the membrane. In lentiviruses, the matrix domain interacts with the long cytoplasmic tail of the viral envelope transmembrane protein inserted into the membrane of the cell.^{158,159} The I domain, an amino acid sequence contained in the nucleocapsid portion of the Gag polypeptide, participates in the Gag-Gag interactions to promote protein polymerization and also appears to be required for incorporation of the Gag-Pol precursor into virions.^{158,159} The nucleocapsid domain of the Gag polypeptide interacts with viral genomic RNA through specific (sequence-specific nucleic acid binding) and nonspecific (interaction of basic residues with RNA) mechanisms and plays an important role in RNA binding, dimerization, and encapsidation and in facilitating Gag protein interactions and packaging into tight complexes.^{98,158,159}

The interactions of these three domains in the precursor protein thus lead to assembly and emergence (but not release) of the viral "bud" from the cell surface.⁴¹³ On electron microscopy, large, electron-dense patches of Gag multimers, visualized under the plasma membrane, deform the membrane outward as they grow. More advanced intermediates appear as spheres connected to the cell by a thin stalk. During the

process of budding, substantial amounts of cellular surface antigens, such as β_2 -microglobulin and HLA-DR, are incorporated into the viral envelope. Additionally, during the process of virion assembly, host-cell proteins may be incorporated into the virion. For example, in HIV-1, a host-cell protein, cyclophilin A, interacts with the Gag polyprotein to form a complex in the virion core.^{157,521} This host factor appears to be required for the formation of infectious virions, and it may play a role in early events after viral entry, as discussed earlier.⁵¹⁵

In addition to the capsid, nucleocapsid, and matrix protein domains, other polypeptide segments that are required during the late stages of viral assembly are contained in the Gag polyprotein. They are referred to collectively as “late assembly” or “L” domains, and they are found in both lentiviruses and oncoviruses. In lentiviruses, the C-terminal portion of Gag (p6) includes a highly conserved amino acid motif that is needed to recruit the cellular machinery required for efficient release of budding virus from the cell membrane.^{413,475,495,562} The Gag protein of oncoviruses also contains a late domain, although it is located in the N-terminal region of the protein.⁴⁹⁵ Some investigators have suggested that these domains engage in interactions with host proteins that are located at the plasma membrane and that facilitate final release of the budding virus from the cell.

In HIV-1, the late domain is thought to interact with the cellular protein ubiquitin. Ubiquitin is a small protein present in cells that, together with cellular proteasomes, is involved in collecting or destroying cellular proteins that are damaged or no longer needed; it exists in cells as a free molecule or is covalently attached to lysines in a variety of proteins. When a protein is linked to multiple ubiquitin molecules (polyubiquitination), the protein becomes targeted for degradation by cellular proteasomes. However, when a protein is linked to a single ubiquitin molecule (mono-ubiquitination), instead of degradation, protein function is modulated; for example, mono-ubiquitination of plasma membrane receptor proteins promotes internalization and downregulation of the receptor through endocytosis in a nonproteolytic process that has some similarities to virus budding. After protein degradation occurs, the ubiquitin molecule is recycled as a free molecule. HIV-1 particles have been shown to contain ubiquitin, predominantly as a free molecule, but 2% to 5% of the Gag-derived, L domain protein p6 is mono-ubiquitinated.⁴⁹⁵ One hypothesis is that the late domain of Gag contains an amino acid sequence that binds to residues on the ubiquitin ligase enzyme and thereby results in mono-ubiquitination of the Gag protein. The Gag-ubiquitin conjugate then may attract undefined cellular factors, perhaps those normally involved in endocytosis, that trigger release of the retrovirus from the cell membrane.⁴¹³ In the absence of the late domain, an infected cell becomes covered with virus that remains tethered to the plasma membrane by narrow stalks.

Maturation of the virion requires cleavage of the Gag precursor by the virally encoded protease and triggers structural changes that produce mature virions with the characteristic spherical oncoviral or cylindric lentiviral capsid. The Gag polyprotein gives rise to the following: the matrix protein, which lines the inner face of the viral membrane; the capsid protein, which forms a core shell surrounding the viral RNA genome and its associated proteins; and the nucleocapsid protein, which coats and condenses the RNA genome. This step occurs concomitantly with or immediately after the external budding process.

Diagnosis

Detection of retroviral antibody has been the test most widely used to diagnose infection in older children and adults. However, because of transplacental passage of maternal antibody, antibody testing during infancy (children <18 months) is not diagnostic of infection, and direct viral detection methods are necessary for establishing the diagnosis. Additionally, during primary infection, a window period exists during which ongoing viral replication is detectable by virologic tests, but antibody tests will be negative or indeterminate because a detectable antibody response has not yet developed.

Antibody testing for retroviruses most frequently involves the use of an initial screening test followed by performance of a more specific confirmatory test. Initial screening generally involves the detection of viral antigens from disrupted whole virus or synthetic or recombinant

viral antigens in an enzyme-linked immunosorbent assay (ELISA). A positive ELISA is confirmed by the more specific immunoblot (or Western blot), which measures the presence of antibodies to various virus-associated proteins, both structural and nonstructural. Viral antigens (from disrupted whole virus or synthetic or recombinant antigens) undergo electrophoresis through polyacrylamide gel to separate the antigens by size. The separated antigens then are transferred to nitrocellulose paper, incubated with the patient's serum, and subsequently incubated with enzyme-linked antihuman antibody and chromogenic substrate, which results in visible bands where patient antibodies are bound by antigens. Analysis of band patterns permits more specific identification of the virus. Other techniques used to measure antibodies to retroviruses include indirect immunofluorescence assay (IFA), radioimmunoprecipitation assay (RIPA), and biologic assays for antibody to envelope glycoproteins (neutralization or syncytium inhibition assays).

Because antigenic differences exist between HIV-1 and HIV-2, HIV-1 screening tests are not reliable for the detection of HIV-2. Commercial HIV-1 and HIV-2 combination assays are available that have high sensitivity for detection of both viruses; a supplemental immunoblot assay is used to confirm the viral subtype.^{91,325} Serologic diagnosis of HTLV infection is similar to that of HIV and involves the use of a screening enzyme immunoassay (EIA) and confirmatory immunoblot or RIPA. However, these tests do not distinguish between antibodies directed at HTLV-1 or HTLV-2.⁹⁰ In patients with positive serology, virologic detection tests, such as proviral amplification by polymerase chain reaction (PCR) or viral isolation, have been used.¹¹⁵ Assays containing several synthetic peptides and recombinant proteins have been developed and appear to be capable of differentiating between HTLV-1 and HTLV-2.^{65,454}

Direct detection of virus by culture is intensive, expensive, and time-consuming; several weeks often are required for results. The ability to isolate HTLV and HIV depends on the patient's disease state, immune status, and viral load. The ability to culture retroviruses has been improved by cocultivation of patient cells with human peripheral blood mononuclear cells that have been stimulated *in vitro* with mitogens (e.g., phytohemagglutinin) and growth factors (e.g., IL-2), as well as by removal of patient CD8+ (suppressor) cells from the coculture. In infants and children, the small volume of blood available for culture and the low virus load in some cases may render virus isolation challenging.

Other methods used for detecting virus include (1) antigen capture assays to detect free circulating viral antigens (e.g., p24 HIV-1 core antigen), (2) IFA and immunohistochemistry to detect viral antigens in tissue, (3) detection of viral nucleic acids by Southern blot analysis, (4) *in situ* hybridization or dot blots, (5) PCR to detect proviral DNA in leukocytes or tissue, and (6) assays to detect viral RNA in plasma or other fluids. DNA PCR can be used to quantitate virus and is highly sensitive because it is capable of amplifying tiny quantities of viral nucleic acids enzymatically to detectable levels with a system of specific nucleotide primers and probes. This technique can be modified to detect viral RNA by using reverse transcription to convert viral RNA to DNA and by performing PCR on the DNA product or by using other techniques such as branched-chain amplification or nucleic acid sequence-based amplification.^{75,406,488}

ONCOVIRUSES: HUMAN T-CELL LYMPHOTROPIC VIRUS TYPES

Human T-Cell Lymphotropic Virus Type I

In 1980, HTLV-1 was reported as having been isolated from lymphocytes from a patient with cutaneous T-cell lymphoma, becoming the first oncoretrovirus to be described as infecting and causing disease in humans.⁴²⁶ HTLV-1 is now recognized as the causative agent of not only ATLL but also HTLV-associated HAM/TSP and uveitis and is strongly associated with a variety of inflammatory and infectious disorders⁵⁷⁷ (Table 192A.1), including autoimmune disorders, pneumonitis, tuberculosis, bronchiectasis, and, particularly in children, a severe infectious dermatitis. Unlike HTLV-2, in which coinfection with HIV-1 is associated with a survival benefit, HIV-1 and HTLV-1 coinfections are associated with reduced survival and possible increased risk for malignancies, HAM/TSP, and other neurologic disease.^{39,41}

TABLE 192A.1 Basis for and Lifetime Risk for Diseases Associated With Human T-Cell Lymphotropic Virus Type 1

	EPIDEMIOLOGIC EVIDENCE			BIOLOGIC EVIDENCE		
	Case Reports or Case Series	Case-Control Studies	Cohort Studies	HTLV-1 Present in Lesions	Animal Model	Lifetime Risk for Developing (for HTLV-1 Carriers) (%)
Malignant Diseases						
ATLL	+	+	+	+	+	1–5 ^a
Cutaneous T-cell lymphoma	+			+		
Inflammatory Syndromes						
HAM/TSP	+	+	+	+	+	0.3–4 ^a
Uveitis	+	+		+	+	
Pulmonary disease	+					
Arthritis/arthropathy	+	+		+	+	
Polymyositis	+			+	+	
Sjögren syndrome	+			+	+	
Infectious Complications						
Infective dermatitis	+					
Tuberculosis	+	+				
<i>Strongyloides stercoralis</i>	+	+	+			
Crusted scabies	+					

^aFor HTLV-1–associated diseases in general, including ATLL, HAM/TSP, uveitis, arthritis/arthropathy, and polymyositis, lifetime risk approaches 10%.
 ATLL, Adult T-cell leukemia/lymphoma; HAM/TSP, HTLV-1–associated myelopathy/tropical spastic paraparesis; HTLV-1, human T-cell lymphotropic virus type 1.
 Modified from Verdonck K, Gonzalez E, Van Dooren S, et al. Human T-lymphotropic virus 1: recent knowledge about an ancient infection. *Lancet Infect Dis.* 2007;7:266-281.

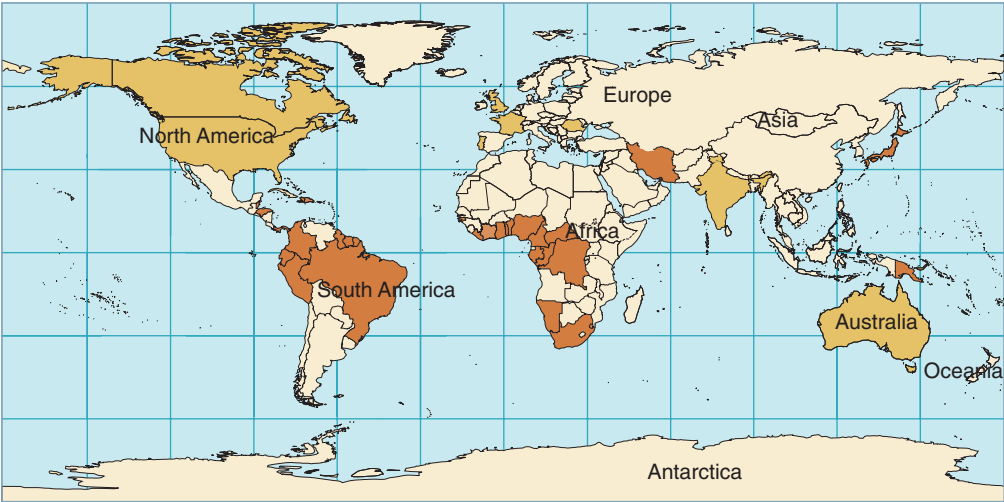

FIG. 192A.4 HTLV-1 epidemiology map. (From Proietti FA, Carneiro-Proietti AB, Catalan-Soares BC, Murphy EL. Global epidemiology of HTLV-I infection and associated diseases. *Oncogene.* 2005;24[39]: 6058-6068.)

Epidemiology

Although its disease implications are clear, most HTLV-1 infections are asymptomatic. It is estimated that 15 to 20 million persons are infected globally.³⁹⁹ HTLV-1 is found in human populations around the world; however, its distribution is highly clustered, with highest prevalence in Japan, the Caribbean, and parts of tropical Africa and South America.⁴⁴⁰ (Fig. 192A.4). Southwestern Japan, in particular, has the world’s highest HTLV-1 prevalence, with rates as high as 37% in some communities,^{364,586} whereas in much of Europe and North America, HTLV-1 rates are very low (<1%).⁵²⁷

Seven subtypes of HTLV-1 have been identified^{550,551}: HTLV-1a is termed Cosmopolitan, and although its origins are in Africa, it is most widely distributed globally. Other subtypes include Australo-Melanesian subtype HTLV-1c and Central African subtypes HTLV-1b, HTLV-1d, HTLV-1e, HTLV-1f, and HTLV-1g.^{550,551,558} The Cosmopolitan group

has been divided further into five subtypes based on LTR sequencing: Transcontinental (A), Japanese (B), West African (C), North African (D), and Black Peruvian (E).^{77,78} Transcontinental, subtype A, the most widespread, has been isolated from Japan, the Caribbean basin, South America, India, Iran, far-eastern Russia, and South Africa. Subtypes B and C are more restricted geographically, with subtype B found primarily in Japan and rarely in India and subtype C found in West Africa and the Caribbean basin. Subtype D has been identified in Morocco, Algeria, and elsewhere in North Africa. Subtype E, the most rare of the Cosmopolitan subtypes, was characterized from two Peruvians of African heritage.^{77,78}

Phylogenetic data indicate substantial similarity between all HTLV-1 subtypes, with the exception of the Australo-Melanesian subtype HTLV-1c, which appears to have undergone a lengthy independent evolution separate from the other strains.^{550,551} Molecular clock studies suggest that HTLV-1a, HTLV-1b, HTLV-1d, and HTLV-1e appear to

have diverged in Africa from precursor primate T-cell lymphotropic virus type 1 (PTLV-1) between approximately 21,100 and 5300 years ago, with HTLV-1f a more recent emergent approximately 3000 years ago.^{550,551} Phylogenetic studies,^{550,552,556} along with the fact that Africa is the only continent where all PTLVs have been found (HTLV types 1 to 4 and their simian counterparts simian T-lymphotropic viruses [STLV] types 1 to 3),⁵⁵⁸ suggest PTLV originated in central Africa.^{550,552,556,558}

Growing interest in the population impacts of HTLV-1 in Africa have yielded new epidemiologic data from the continent in recent years.²¹³ A recent meta-analysis of data from 25 African countries yielded HTLV-1 seroprevalence ranging from 0% to 17%, with highest rates in West and Central Africa and lowest rates (0%) in many North African countries.¹⁵⁶ Within a given locale, risk varies among groups of individuals; in a Cameroonian study, HTLV-1 prevalence in individuals who had been bitten by an NHP was 8.6%, whereas in matched controls the rate was 1.5%.¹⁵³ Data from equatorial Africa indicate that a north-south gradient exists for HTLV-1 prevalence, with rates of 0% to 2% in Chad, the northern Central African Republic, and northern Cameroon to 5% to 10% in forested areas of Gabon, Equatorial Guinea, southern Cameroon, and southern Central African Republic.³⁰¹ Indeed, a cross-sectional survey in southern Central African Republic yielded a 7.4% prevalence of HTLV-1,⁴¹⁹ as well as suggestions that HTLV-1 was likely transmitted in Central Africa during the 1940s and 1950s when prophylactic injections of pentamidine were used as chemoprophylaxis for African trypanosomiasis.^{420,419}

The broad dissemination of HTLV-1 beyond Africa was likely driven by the slave trade, along with increased mobility among populations, with HTLV-1a being introduced to Japan, the Middle East, North Africa, and the Americas.^{170,171,179,491,551,552,558} Japan's southern islands of Kyushu and Okinawa have the world's highest HTLV-1 prevalence, more than 10% in the general population,^{268,336,360,505} although transmission rates to infants have fallen greatly with the institution of exclusive breastfeeding by HTLV-1 carrier mothers.⁵⁰⁵ Data from a nationwide survey of blood donors in Japan showed 2% and 1.8% HTLV-1 prevalence rates in females and males, respectively, with significantly higher rates in the 40- to 64-year-old age group than in younger individuals.⁴⁶⁹ Less is known about HTLV-1 rates in other parts of Asia where HTLV screening of blood donations is not routinely done, and rates vary, with available data showing rates of 0.1% to 1% in Iran and Taiwan, and as high as 2.6% in large cities in China.^{1,303,567,584} In Oceania, HTLV-1 is endemic to Irian Jaya, Papua New Guinea, Vanuatu, and the Solomon Islands, with between 1% and 2% of the indigenous population carrying HTLV-1c.^{82,166,509} In Australia, HTLV-1 is relatively common in Aboriginal populations, particularly in central Australia.¹³⁷

The origins of HTLV-1 in the Americas have been controversial, with some data, including HTLV-1 isolated from an Andean mummy, suggesting introduction of HTLV-1 in ancient times through migration of persons across the land bridge once connecting Asia with Alaska.^{77,78,551} Molecular clock estimates and phylogenetic studies, however, suggest that HTLV-1 arrived in the Americas first with the slave trade, and then again with Japanese immigration in the early 1900s.^{77,78,421} Indeed, where HTLV-1 is prevalent in the region, including Jamaica and Trinidad and Tobago (up to 6% in both),^{77,78,366} Martinique, Guyana, French Guiana, Suriname, Colombia, and northern Brazil, HTLV-1 is especially frequent among descendants of African slaves.^{57,433,526} Studies of blood donors in Argentina and Peru demonstrate HTLV-1 rates up to 2%,^{174,262,286} with higher prevalence in indigenous peoples.^{191,409,467,601} HTLV-1 is generally rare in Central and North America, although there, too, notable rates (1–3%) have been seen in some indigenous groups.^{409,191,558}

In Western Europe, HTLV-1 infection is generally rare,⁵⁵⁸ with infections clustered in specific risk groups. In a British sexual health clinic, 0.7% of an HIV-infected population was coinfecting with HTLV-1, with 80% of HIV-1 or HTLV-1 coinfecting persons being females born in either sub-Saharan Africa or the Caribbean.¹⁰⁵ In a comprehensive survey of individuals infected with HTLV-1 in England and Wales between 2002 and 2004, more than 50% were of Afro-Caribbean origin.¹³³ In some parts of Western Europe, HTLV-1 is nearly nonexistent; in a survey of young heroin users in Spain, no HTLV-1 infections were recorded.¹¹⁹ Eastern European rates may be higher, between 0.5% and 1%,⁴¹⁴ with Romania considered an endemic area for HTLV-1 and its

associated pathologies, particularly ATLL.³⁰⁹ However, in Eastern Europe, too, rates vary, with a recent survey of HTLV rates in IDU in Estonia yielding a 0% prevalence.²⁴⁷

Modes of Transmission

Unlike HIV, HTLV-1 is not produced by infected T cells in appreciable quantities. Plasma HTLV-1 viral loads are virtually undetectable,²³² and its efficiency of transmission is accordingly much lower than that of HIV. HTLV-1 is transmitted by cell-to-cell contact as a provirus.²³² Hence its modes of transmission are those in which T cells themselves are transmitted and cell-to-cell interactions possible²⁴⁹—most commonly from mother-to-child during breastfeeding; parenterally through transfusion of infected cellular blood products or reuse of needles and syringes; and, much less efficiently,³⁹⁹ through sexual intercourse. In areas endemic for HTLV-1, infection generally clusters in communities. This, along with the observation that seroprevalence declines in subsequent generations of people migrating from endemic to nonendemic areas,^{343,344} suggest that biologic or social cofactors exist that affect HTLV-1 transmission.³¹⁶

Mother-to-child transmission. Occurring in 4% to 22% of infants born to HTLV-1–positive women,⁵⁵⁹ mother-to-child (“vertical”) HTLV-1 transmission is the most important route of HTLV-1 acquisition⁵⁶⁸ because, in addition to being the most common manner in which HTLV-1 is transmitted,²⁴⁹ HTLV-1 infection in early life is associated with the development of adult T-cell leukemia/lymphoma (ATL), a key HTLV-1–associated pathology, later in life; indeed, approximately 1% to 5% of children infected through vertical transmission will develop ATL.^{441,187,162} Vertical transmission rates as great as 31% have been seen in mothers coinfecting with *Strongyloides* spp.⁵⁵⁹ Vertical transmission of HTLV-1 infection is the principal mode of infection in children,⁵⁶⁸ with more than 90% of HTLV-1–seropositive Japanese children having seropositive mothers and most perinatal HTLV-1 transmission occurring through breastfeeding.³⁷² Transplacental transmission is believed to be unlikely, given the near absence of proviral HTLV DNA in umbilical cord lymphocytes of HTLV-infected mothers.^{465,545} Indeed, prenatal and perinatal transmission are likely minor contributors to the entirety of vertical HTLV-1 transmission, with evidence implicating breastfeeding, particularly prolonged breastfeeding, as the major source of perinatal transmissions.^{372,512} In a sample from a neonatal screening program in Brazil of 42 infants born to HTLV-positive mothers, none was PCR positive for HTLV-1 or HTLV-2 at birth.⁴⁴⁹ Globally, fewer than 3% of HTLV-1–exposed infants who are fed formula are subsequently diagnosed with HTLV-1 infection.¹⁷ For breastfeeding infants, duration of breastfeeding, as well as the provirus load in breast milk and HLA class I concordance between mother and child,⁵⁰ is associated with increased transmission risk.^{50,295} Approximately 5% of breastfeeding infants become infected after 3 months of breastfeeding, whereas up to 40% of infants become infected when breastfeeding is prolonged.¹⁷ The median time to infection in a Jamaican cohort was 11.9 months,¹⁶³ and the passive transfer of maternal HTLV-1 is believed to be protective against infection.^{17,449,512} Other associations with risk for vertical transmission of HTLV-1 include female gender of the child, older maternal age, long duration of membrane rupture (>4 hours), and lower maternal income.^{220–222,257,506,545,574,575}

In some countries where HTLV-1 is endemic, including Japan, Brazil, and Martinique, HTLV-1 is screened for either in pregnancy or in neonates.^{10,451,450,507} Policy in these countries and in other similarly well-resourced settings is for HTLV-infected mothers to completely avoid breastfeeding and for formula to be provided for HTLV-1–exposed infants. If breastfeeding is unavoidable, weaning before 6 months will prevent most HTLV-1 infections. Indeed, where this approach has been put into practice, HTLV prevalence has dropped sharply.^{219,257}

Yet, although complete cessation or limiting breastfeeding has clear advantages for preventing perinatal transmission of HTLV-1, no international guidelines (World Health Organization, United Nations Children's Fund, Centers for Disease Control and Prevention [CDC], or similar) exist for breastfeeding and HTLV-1 prevention in resource-poor settings, which include most developing countries and most HTLV-1–endemic settings, particularly sub-Saharan Africa.¹⁵ Although clear risks exist in HTLV-1 infection, including severe disease (e.g., ATL

or HAM/TSP) in approximately 5% to 10% of infected persons and many other morbidities of variable impact, well-defined and substantial risks exist to both early weaning and formula-feeding,⁵³³ particularly in resource-poor countries, yet high HTLV-1 prevalence is found in pregnancy in many settings.^{17,148,553} Southeast Gabon, for example, has HTLV-1 prevalence in pregnancy in excess of 5%, one of the highest rates in the world,¹⁴⁸ whereas recent data from Malawi indicating maternal HTLV-1 prevalence of 2.6% demonstrate that mother-to-child transmission risks in Africa exist outside the previously recognized areas of West and Central Africa.¹⁵⁶

Complicating issues for HTLV-1 transmission prevention in resource-poor settings is the recognition of breastfeeding as one of the most powerful child survival interventions, a cornerstone of efforts to reduce mortality worldwide in children younger than 5 years,²⁴⁸ although African studies on prevention of perinatal HIV transmission have shown serious morbidity and mortality risks to be associated with formula-feeding. In Botswana's Mashi trial, cumulative mortality from all causes at 7 months was significantly higher (9.3% vs. 4.9%) in infants randomly assigned to formula-feeding versus those assigned to breastfeeding plus zidovudine (AZT). HIV-free survival at 18 months was equivalent between the two groups, showing that the early mortality increase seen with formula-feeding negates the benefits of reduced HIV transmission.⁵²² Work in Guinea-Bissau, where HTLV-1 prevalence is 5% and socioeconomic indicators are among the most austere in Africa, has shown increased risk for diarrheal diseases and mortality among children weaned before 12 months of age.^{553,554} Additionally, during an outbreak of diarrhea in Botswana in early 2006, more than 22,000 Botswanan infants experienced diarrhea (in contrast to just more than 9000 over the same period in 2005), and the number of deaths in children younger than 5 years of age increased by 20-fold.¹⁰⁷ Virtually all deaths in the diarrheal cohort were in formula-fed infants, suggesting a lack of protective immunity in formula-fed versus breast-fed infants, a finding consistent with the long-appreciated immunologic benefits of breastfeeding. Malnutrition and growth failure are also more common in formula-fed than breast-fed HIV-exposed infants.²⁷³

It is unclear to what extent cesarean delivery or the use of antiretroviral drugs during and after delivery help prevent perinatal HTLV-1 transmission, as they have been shown to do with perinatal HIV transmission. Indeed, there have been no prospective studies of either antiretroviral therapy (ART) or delivery mode to evaluate the potential for augmenting perinatal HTLV-1 transmission efforts.^{77,78} In a Brazilian study, none of the HTLV-1-exposed infants subsequently diagnosed with HTLV-1, including both those born vaginally and by cesarean delivery, were PCR positive for HTLV-1 shortly after birth, yet all had breast-fed, supporting perinatal HTLV-1 transmission as postnatal via breastfeeding.⁴⁴⁹ Yet the finding that the duration of rupture of the membrane is associated with transmission of HTLV-1 suggests that some percentage of transmissions may occur intrapartum, and some HTLV-1-infected infants by maternal report did not breastfeed. The utility of cesarean delivery in preventing perinatal HIV transmission is chiefly in mothers with a detectable viral load at term, especially when viral load is high.⁴¹¹ Currently, in most settings globally, HTLV-1 proviral load testing is not readily available for incorporation into decisions on mode of delivery, nor is formal guidance accessible on the use of either HTLV-1 proviral load testing or cesarean delivery in the management of perinatal HTLV-1 prevention.

Parenteral transmission. Parenteral transmission by transfusion and intravenous drug use is well documented and appears to be the most efficient mode of transmission, with an estimated 44% chance of infection occurring in those receiving HTLV-1-infected cellular products.³¹⁹ Comparative rates of transmission of HTLV-1, HTLV-2, and HIV-1 were evaluated retrospectively in a large repository of US blood donor serum from the Transfusion Safety Study.¹³⁰ Consistent with a requirement for cell-to-cell contact for transmission of HTLV and in contrast to HIV-1, transmission of HTLV-1 and HTLV-2 was observed only with the transfusion of cellular blood components. Infectivity appeared to decrease with an increasing period of blood storage; no apparent transmission occurred after the transfusion of components stored more than 10 days, a finding suggesting that the known decrease in the ability of donor lymphocytes to be activated or to proliferate with storage

renders the cells noninfectious. In this study, rates of transfusion-related transmission of HTLV-1 and HTLV-2 were similar; approximately 27% of recipients of blood components from seropositive donors became infected. In contrast, 89% of the recipients of HIV-1-positive blood became infected, regardless of the blood product component type, and no effect of storage on transmission risk was seen. The median time to seroconversion after the transfusion of HTLV-1-contaminated blood products is 51 to 65 days.⁴⁴⁰

Over the past two decades in Japan, the United States, Canada, and much of South America and Western Europe, screening of blood donors for HTLV-1 and HTLV-2 has dramatically reduced the number of transfusion-associated HTLV infections and has contributed to reductions in HTLV prevalence in the general population.^{120,133,440,558} Because many blood donors are repeat donors, exclusion of HTLV-infected donors from the eligible pool yields a resource-use benefit over time for blood banks, with fewer HTLV-positive tests seen year to year after instituting screening.¹³³ In the United Kingdom, where screening was instituted in 2002, by 2004 the number of HTLV-positive screens had fallen by more than 80%.¹³³

However, in countries in which screening of blood for HTLV-1 and HTLV-2 is not performed, transfusions continue to provide an important source of infection. Patients with transfusion-dependent conditions, such as sickle cell disease, are especially at risk. In a study of hospitalized children in Gabon in Africa, multiple blood transfusions secondary to complications of sickle cell disease were as predominant a mode of transmission of HTLV-1 as perinatal transmission.¹²⁸ Similarly, in Martinique, HTLV-1 seroprevalence in patients with sickle cell anemia was 10% versus 1% to 3% in blood donors, and HTLV-1-seropositive patients had received more transfusions than had seronegative persons.⁴⁶⁷

Case reports detail multiple cases—in endemic countries or involving donors from endemic countries—of HTLV-1-associated disease after solid organ or bone marrow transplantation.³²⁵ In all these cases, HTLV-1-associated disease occurred within a brief time (<2 years) after transplantation; it is likely that immunosuppressive treatment facilitates accelerated replication of HTLV-1.⁵²⁵ In Japan, North America, and many European countries, organ donors are now screened for HTLV-1 infection.^{18,331}

Intravenous drug use is a notable source of other parentally transmitted infections, such as HIV. Somewhat paradoxically, however, HTLV-1 is rarely detected in injection drug users,^{119,440} especially younger cohorts.¹¹⁹ A Spanish study of young injection heroin users showed no HTLV-1 in 981 injection drug users screened, whereas 27 individuals were HTLV-2 positive.¹¹⁹ This study's HTLV-2 findings are not novel because HTLV-2 is considerably more commonly detected in injection drug users than HTLV-1,^{440,558} and in Spain, almost all HTLV-2 infections are diagnosed in such users.^{43,305,524} Some cohorts, however, defy this trend, with HTLV-1 prevalent among injection drug users in New York and Brazil,^{149,558} and sharing needles is considered an effective transmission route for HTLV-1.¹⁸⁶

Sexual transmission. Sexual transmission is a significant source for acquisition of HTLV-1 in adults. In serodiscordant couples, incident infection is low, with one cohort of 30 couples followed for 10 years yielding an HTLV-1 infection incidence estimate of 0.9 per 100 person-years.⁴⁶⁰ Older cross-sectional studies suggested higher transmission efficiency from males to females,^{284,371,440} but more recent cohort studies have shown no significant difference in male-to-female transmission compared with female-to-male transmission.⁴⁶⁰ Nonetheless, HTLV-1 rates in settings worldwide are higher in females than in males, as are rates in older cohorts than in younger ones, suggesting a cumulative risk over time.^{481,505} The infected individual's proviral load is likely an important factor in risk for transmission between discordant partners. In the Retrovirus Epidemiology Donation Study, which has enrolled volunteer blood donors from five participating blood centers since 1988, HTLV-transmitting men had proviral loads higher than those of nontransmitters.²⁵⁶ Transmitting men also tended to have higher antibody titers against various viral proteins than did nontransmitters; in general, antibody titers correlated highly with proviral load.²⁵⁶

Similar to other sexually transmitted infections (STIs), HTLV-1 seropositivity is associated with higher numbers of lifetime sexual partners, presence of genital sores, paying for or receiving money for

sex, and anoreceptive intercourse among men who have sex with men.^{28,43,440,490,572} In studies from several different countries, prevalence of HTLV-1 has been found to be elevated in female sex workers.^{127,192,576} In these studies, the lack of consistent use of condoms, the duration of prostitution, older age, infection with *Chlamydia trachomatis* or syphilis, antibody to herpes simplex virus type 1, and concomitant HIV-1 infection were associated with elevated HTLV-1 prevalence.^{192,378} Among sex workers in Peru, condom use has been shown to protect against HTLV-1c infection.^{192,531} An increased risk for HTLV-1 seropositivity has been observed in persons attending clinics that treat STIs.^{152,264,378,572} In such clinics in the United States, HTLV seropositivity ranges from 0.18% to 2%; in the United Kingdom, rates in similar clinics were between 0.5% and 1%,^{105,133} well higher than rates in the general population of less than 0.01% in both settings.

Descriptive studies have suggested that ecologic factors may influence the rate of seropositivity in a population; for example, residence in a lower altitude, tropical environment was associated with higher rates of seropositivity in some reports.^{316,343,344} A role for insect vectors, such as mosquitoes, was postulated. However, no evidence has shown that retroviruses can replicate in arthropods, and any hypothesized insect-borne transmission would need to occur mechanically by the mouth parts of biting insects that were contaminated with a significant amount of infected and infectious lymphocytes; such transmission, if it occurred, would be expected to be very unusual.¹⁵⁴ However, a very strong epidemiologic association exists between infection with *Strongyloides* and HTLV.¹⁸⁵ A case-control study from Guadeloupe ties together *Strongyloides* infection and the socioeconomic and environmental risk factors (i.e., low socioeconomic status, low educational level, and agricultural activity) associated with many HTLV clusters noted in diverse tropical settings worldwide, suggesting that *Strongyloides* infection may increase susceptibility to HTLV infection and be responsible in some settings for both the notable clustering of HTLV within endemic areas and the decrease in HTLV prevalence noted in migrant communities from endemic areas over time.¹⁰⁶

Disease Associations

In HTLV-1-infected individuals, persistent viral infection and antigen production elicit a strong humoral and cellular immune response that results in high antibody titers to HTLV-1 structural and regulatory proteins and increased circulating activated HTLV-1 Tax protein-specific cytotoxic T lymphocytes.^{109,236} In addition, even in asymptomatic patients, spontaneous *in vitro* proliferation of lymphocytes is observed.²⁷¹

Early in the course of primary infection, the HTLV-1 proviral load is high but becomes controlled rapidly. Within 90 days of primary infection, a narrow range of proviral load is observed in an individual that generally stays relatively constant over the course of time.^{318,395,519} Antibody titer is highly correlated with proviral load after the initial set point is reached. The HTLV-1 proviral load in asymptomatic HTLV-1 carriers can be as high as 5% of all peripheral blood mononuclear cells, and it is particularly high in individuals with HAM/TSP, in whom as many as 20% of peripheral blood mononuclear cells can be infected.^{318,361} A high peripheral blood proviral load appears to predate the development of neurologic and ophthalmologic HTLV-1-associated disease entities.

Although most individuals infected with HTLV-1 will remain symptom-free lifelong, regardless of age at time of infection or infection route, between 5% and 10% of infected individuals will develop HTLV-associated illness, which can be, especially in the case of ATL and HAM/TSP, extraordinarily severe.³⁸¹ Indeed, HTLV-1 may be a prototype for other retroviruses yet to be discovered that predispose to the development of active diseases with long latency after exposure at birth or early in life.

A variety of less intense clinical manifestations have been noted in HTLV-infected individuals, including uveitis, other rheumatic and neurologic conditions, pulmonary disease, other coinfections, and, especially in children, infective dermatitis.^{25,81,425,440,558} Some manifestations of HTLV-associated disease are different in children and adolescents than in adults; HAM/TSP in children, for example, while rare, usually is associated with infective dermatitis and, unlike most cases in adults, is rapidly progressive.²⁵ Studies from Brazil of recently diagnosed individuals indicate that neurologic, ocular, and rheumatologic symptoms may be the first manifestations of HTLV-1 infection,⁴²⁵ and in Brazilian

cohorts with long-standing HTLV-1 infection, HTLV-1-infected individuals were more likely than controls to report extremity weakness or hand or foot numbness, arthralgia, nocturia, and oral findings such as gingivitis, periodontitis, or dry mouth.⁸¹

Adult T-Cell Leukemia and Other Malignancies

HTLV-1 is a truly oncogenic virus, with its prototype manifestation being ATLL.³⁸¹ First described in Japan by Takatsuki in 1977,⁵⁴¹ and the first disease to be causally linked to HTLV-1 infection, ATLL is a malignancy of mature peripheral T lymphocytes.²³⁸ Approximately 3% of HTLV-1 carriers will ultimately develop ATLL,³⁸¹ and ATLL is much more common in individuals who are thought to have acquired HTLV-1 infection perinatally.⁵⁴² After infection, HTLV-1 produces cell immortalization through Tax-1, which yields a clonal expansion of HTLV-1-infected T cells in a proportion of asymptomatic carriers who then manifest high proviral loads.^{381,511,542} a risk factor for developing ATLL.^{241,396} Other risk factors include increasing age (a mean of 57 years in Japan) and a family history of ATLL.²⁴²

The distribution of ATLL follows that of HTLV-1, with most cases in southwestern Japan, tropical Africa, the Caribbean, Middle East, Irian Jaya, Papua New Guinea, and parts of South America.⁵⁴¹ In hyperendemic southwestern Japan as many as 9.3% of patients newly diagnosed with hematologic disorders have ATLL,²³⁸ and more broadly in Japan data suggests an incidence of approximately 0.37 per 100 HTLV-1 carrier years.⁴⁹⁴ ATLL epidemiology is similar in endemic areas of the Caribbean such as Jamaica and French Guiana,³⁶⁷ as well as in Brazil and Iran,³⁰⁹ although average age of onset in Africa, Brazil, and the Caribbean is lower (42–49 years), and in both regions ATLL is more common in women than in Japan,^{24,59,428,587,590} where the male-to-female ratio is 1.4:1.³⁰⁹ One hypothesis for the younger age of ATLL onset in the tropics is the presence of *Strongyloides* coinfection. *Strongyloides stercoralis* stimulates clonal expansion of HTLV-1-infected cells in asymptomatic carriers, potentially serving as a cofactor for ATLL development.¹⁶⁹

Outside endemic areas, ATLL is most commonly seen in immigrants from endemic areas, most of whom are assumed to have obtained their HTLV-1 infection perinatally.^{337,339} In Great Britain and France, almost all ATLL cases are seen in first- or second-generation immigrants of African or Afro-Caribbean descent.^{309,337,339} In the United States, the incidence of ATLL is low; cases are seen primarily in immigrants from HTLV-1-endemic areas or in blacks in the southeastern United States, in whom endemic HTLV-1 infection has been documented.⁴⁴⁵ In a study in central Brooklyn, which has a large Caribbean migrant population, the annual incidence of ATLL in African Americans of all geographic backgrounds was approximately 3.1 per 100,000 person-years.²⁸⁸

Given the long incubation period generally associated with ATLL, the condition in children is quite rare. Most cases of ATLL in childhood occur in tropical countries; nearly half of those reported have been from Brazil.^{59,103} Mean age of diagnosis in case reports in the literature is 15 years,^{59,308,427,428} although cases have been diagnosed in children as young as 2 years.^{427,428} In one case series, maternal HTLV-1 serology was positive in 16 of 19 cases where it was available,⁵⁹ with one of the three cases with maternal serology having received a blood transfusion and the other two having been breast-fed by women of unknown serologic status.^{293,427,428} Most cases in children present similarly to cases in adults and, like adult cases, have poor outcomes.⁵⁹

Given substantial diversity in how ATLL presents and evolves clinically, diagnostic criteria developed in Japan are used for classifying the malignancy into four major subtypes.^{309,486} For diagnosis, histologically or cytologically proved lymphoid malignancy must be found, with expression of specific T-cell surface antigens; abnormal CD4⁺ and CD25⁺ T lymphocytes³⁷ with characteristic lobulated nuclei (so-called flower cells, containing monoclonal or oligoclonal HTLV-1 provirus integrated into the cell genome) in peripheral blood (except in the ATLL type), with many asymptomatic HTLV-1 carriers expressing a persistent leukocytosis; and positive serum antibodies against HTLV-1 at the time of diagnosis.³⁰⁹ These criteria are summarized in Box 192A.1. Monoclonal expansion of HTLV-1-infected cells in carriers is directly associated with ATLL onset.³⁰⁹ A method for detecting a persistently infected HTLV-1 monoclonal cell population could serve as a monitoring approach, especially for perinatally infected individuals at highest risk for developing ATLL.³⁰⁹

Why ATLL develops in only a small percentage of HTLV-1-infected individuals, including those infected perinatally and at greatest risk for ATLL, is not completely clear. Although ATLL is clearly linked to the integration of HTLV-1 into every malignant cell,^{337,339} ex vivo studies of ATLL cells indicate lack of expression of viral proteins or RNA, and occasionally defective viral genomes are detected.^{106,337} Because malignant transformation probably is a multistep process, intermediate factors such as the host immune response, oncogenic environmental stimuli, or both, may be involved.²³⁰ Familial ATLL has been documented in several countries, including Japan, the United States, and the United Kingdom,^{337,338,589,590} yet it is not known whether genetic predisposition is involved in the development of ATLL in such cases.^{337,339}

Monoclonal HTLV-1 provirus is found integrated into the DNA of ATLL malignant cells. HTLV-1 is known to transform normal CD4+ lymphocytes in vitro and results in immortalization, high levels of IL-2 expression, and increased expression of the IL-2 α -chain receptor on the cell surface. The presence of excessive receptors for IL-2, a known growth factor for T cells, may be linked to development of the proliferative leukemic process of ATLL.^{587,590} Additionally, the HTLV-1 Tax protein activates the promoters of many genes involved in cell growth and differentiation and interferes with DNA repair functions.³⁶² Indeed, studies of transgenic mice and human CD34+ stem cells suggest that Tax initiates ATLL because leukemia with ATLL features has been induced by Tax expression.^{23,210,431}

One hypothesis is that the continuous proliferation observed in HTLV-1-infected cells may render them more susceptible to spontaneous mutagenesis, as well as to the effect of external carcinogens.² The finding

that persistent clonal expansion of HTLV-1-infected cells precedes the development of ATLL suggests that tumor cells may originate in clonally expanding nonmalignant cells through a multistep process that may include the mutation or deletion of tumor suppressor genes such as *p53* or *p15^{INK4B}/p16^{INK4A}*, which are detected in 30% to 50% of ATLL cases and associated with clinical subtypes and prognosis.^{42,168} Along with affecting tumor suppression genes and reducing DNA repair, Tax downregulates DNA polymerase β , affecting base excision repair⁴² and suppressing nucleotide excision repair.^{118,254} Tax also reduces the activity of telomerase, contributing to changes in chromosome number^{42,168,254}; ATLL cells are usually aneuploid.³²⁸ Accordingly, chromosomal fusions and shortened telomeres are also regularly detected in ATLL cells, perhaps reflecting this decreased human telomerase expression in early transformation stages.^{42,168}

The host immune response also may be involved in malignant transformation because cells may escape immune surveillance by deleting Tax,³⁷ the major target of cytotoxic T cells in HTLV-1 infection.²²⁴ Indeed, HTLV-1-infected patients with ATLL have poorly detectable Tax-specific cytotoxic T-cell activity,^{253,393} which could permit more unrestrained proliferation of infected cells and lead to increased HTLV-1 viral load, higher HTLV-1 antibody levels to non-Tax viral proteins, and, eventually, malignant transformation. HTLV-1 bZIP (*HBZ*) factor gene has growth-promoting activity and is expressed in all ATLL cells,⁴⁶⁴ suggesting *HBZ* also may play a role in cellular transformation and leukemogenesis.^{37,335} *HBZ* expression correlates with provirus load,³⁷ which itself correlates with risk for developing ATLL.²⁵⁹

The Japanese Lymphoma Study Group has defined ATLL in four major subtypes, based on how the condition presents⁴⁸⁶ and for which there are clinical and laboratory criteria (Table 192A.2). The distribution of clinical ATLL subtypes varies geographically. In Japan, most cases are acute ATLL with leukemic manifestations; however, in the Caribbean, most cases are initially of the lymphoma subtype.^{288,289} ATLL frequently presents aggressively, either as a leukemia or with lymph node enlargement without peripheral blood involvement (<1% leukemic cells in peripheral blood).³⁷ Most commonly globally (about 60% of cases),³⁷ ATLL presents acutely as leukemia along with systemic symptoms, organomegaly, and prominent lymphadenopathy.^{337,339} The lymphoma subtype represents 20% of global ATLL cases.³⁷ In both aggressive subtypes, massive lymphadenopathy usually is present, although sparing the mediastinum,³⁷ as are hepatosplenomegaly and multiple visceral lesions, including skin, lung, and gastrointestinal infiltration.³⁷ ATLL cells in vitro express receptor activator of NF- κ B ligand on their surface and, along with

BOX 192A.1 Requirements for Diagnosis of Adult T-Cell Leukemia/Lymphoma

1. HTLV-1 seropositivity
2. Histologically or cytologically proven lymphoid malignancy with T-cell surface antigens present
3. Abnormal T lymphocytes ("flower cells") consistently present in peripheral blood (except for lymphoma subtype of ATLL)
4. Demonstration of clonality of proviral DNA as well as clonal integration of proviral DNA

ATLL, Adult T-cell leukemia/lymphoma; HTLV-1, human T-cell lymphotropic virus type 1.

TABLE 192A.2 Clinical Subtypes of Adult T-Cell Leukemia/Lymphoma: Clinical and Laboratory Findings

	ADULT T-CELL LEUKEMIA/LYMPHOMA CLINICAL SUBTYPE			
	Acute	Chronic	Lymphoma	Smoldering
Percentage With Subtype (%)	55	20	20	5
Survival				
Median	6 mo	24 mo	10 mo	>24 mo
Four-year survival rate (%)	5	27	6	66
Clinical Findings				
Lymphadenopathy	±	±	Yes	No

Skin involvement	±	±	±	±
Bone lesions	±	No	±	No
Bone marrow involvement	±	No	±	No
Laboratory Findings				
Absolute lymphocyte count ($\times 10^9$)	Not definitive	≥ 4	<4	<4
Abnormal circulating lymphocytes (%)	$\geq 5^a$	$\geq 5^a$	≤ 1	$\geq 5^a$
Polylobulated lymphocytes ("flower cells")	Yes	Occasionally	No	Occasionally
Calcium	Normal or elevated	Normal	Normal or elevated	Normal
Lactate dehydrogenase	Normal or elevated	<2 times normal	Normal or elevated	<1.5 times normal

^aIf <5% of circulating abnormal lymphocytes are present, at least one histologically proved tumor lesion from the lungs, skin, or elsewhere is required for diagnosis.

Modified from Verdonck K, Gonzalez E, Van Dooren S, et al. Human T-lymphotropic virus 1: recent knowledge about an ancient infection. *Lancet Infect Dis* 2007;7:266-281.

elevated levels of mononuclear phagocyte colony-stimulating factor, induce the differentiation of hematopoietic precursor cells to osteoclasts.³⁰⁹ The resultant acceleration in bone resorption leads to lytic bone lesions in some cases,^{309,337,339} and, with or without lytic bone lesions, to the prominent hypercalcemia characteristic of acute ATLL.³⁰⁹ Of acute ATLL cases, 20% to 30% present with hypercalcemia at diagnosis and more than 70% manifest hypercalcemia at some point in the illness course.^{309,337,517} ATLL cells also have been found to secrete excessive amounts of parathyroid hormone–related peptide, probably because of Tax-mediated transactivation of the gene for this protein, which also contributes to hypercalcemia.¹³⁹ Skin lesions also are common in acute ATLL,^{337,339} caused by dense skin infiltration by clonal HTLV-1 tumoral cells.^{337,339,588,589} Multiple types of skin lesions have been described, from papules and nodules to erythroderma and ulcerative lesions.³⁰⁹ In some acute ATLL presentations, cutaneous findings dominate the clinical picture; so-called cutaneous ATLL can be challenging to differentiate from mycosis fungoides and Sézary syndrome.^{123,309}

The chronic form of ATLL manifests as lymphocytosis with ATLL cells, often stable for months to years, skin findings, low-grade lymphadenopathy and hepatosplenomegaly, occasional lung involvement and the absence of systemic symptoms, hypercalcemia, and lactate dehydrogenase (LDH) either normal or only slightly raised.^{37,106,108,109,337,487} The central nervous system (CNS) is not involved in chronic ATLL,³⁷ which is separated into favorable and unfavorable subgroups, with the worse prognosis defined by low serum albumin, high LDH or high urea levels, and an elevated expression of Ki-67 antigen.⁵⁸⁶ In smoldering ATLL, the least common ATLL presentation, affected individuals usually do not have symptoms but may have skin rash pulmonary infiltrates, with absence of other visceral involvement.^{37,237,337,339} Cutaneous manifestations of smoldering ATLL often respond to topical steroids, and pulmonary findings may be misdiagnosed as infectious or other processes.^{337,339} Key to the diagnosis of smoldering ATLL versus the chronic form of ATLL is a normal leukocyte count,^{337,339} of which abnormal lymphocytes make up 1% to 5%.³⁷ Although not common, cases have been reported of disease progression from chronic or smoldering ATLL to acute, leukemic manifestations.^{337,339} Table 192A.3 details clinical findings in ATLL presentations.

Although the described classification scheme is used globally as the standard for describing ATLL and its prognosis and treatment, gaps exist in its definitions.³⁷ Given the definition of lymphoma subtype by the presence of fewer than 1% circulating abnormal lymphocytes, patients with aggressive presentations and more than 1% circulating abnormal lymphocytes are classified as having acute ATLL, even when bulky lymphadenopathy or visceral involvement is present. Current data indicate that such patients with substantial lymph node or organ involvement do not respond to antiviral therapy alone, as do leukemic ATLL patients with less prominent lymph node and organ involvement,³⁷ suggesting, from a treatment perspective, that a third aggressive category

may exist and be in need of description. As well, debate is ongoing about how to classify patients with isolated circulating abnormal lymphocytes (>5%). In the current approach, they are classified as having smoldering ATLL, although data suggest that this group of patients has outstanding long-term survival,²²⁹ in contrast to patients with smoldering ATLL with infiltration of skin or lung.⁵¹⁰

Individuals with ATLL are immunosuppressed, with severely impaired T-cell-mediated immunity.^{337,339,571} Opportunistic infections are common and are a common cause of mortality;³⁸¹ indeed, most deaths in ATLL patients are due to opportunistic infections and complications of opportunistic infections, such as hypercalcemia.³⁸⁹ *S. stercoralis* infection is commonly present, and a hyperinfection syndrome may develop, accompanied by gram-negative sepsis, with a mortality rate of greater than 70%. As mentioned earlier, evidence suggests that *S. stercoralis* infection may be a cofactor for HTLV-1–induced leukemogenesis.³⁰⁹ Other common opportunistic infections include bacterial infections, *Pneumocystis* pneumonia, and serious fungal infections. Findings indicative of poor survival include age older than 40 years, increased tumor bulk, poor performance status, high LDH level, hypercalcemia, and the presence of clones of cells containing multiple or defective copies of the HTLV-1 provirus.^{11,449} The CNS, which is affected in 2.5% to 10% of patients, can act as a sanctuary and has been found to be an important site for relapse when chemotherapy is given to treat ATLL.⁴¹⁵

The prognosis and treatment of ATLL depend on the subtype, and for prognosis purposes, ATLL is classified into low-, intermediate-, and high-risk groups based on age (high risk >70 years of age), stage, performance status and biochemical markers (serum albumin <3.5 g/dL, and serum IL-2 >20,000 U/mL²⁵⁹), and median survival times are estimated at 16.2, 7.3, and 3.6 months, respectively²⁶⁰). Survival rate varies markedly by subtype, with a 4-year survival of 66% for smoldering ATLL, 27% for the chronic form of ATLL, and 5% to 6% for acute and lymphoma types. Aggressive ATLL presentations (acute and lymphoma) are among the most severe lymphoproliferations known to medicine³³ and have very poor prognoses for multiple reasons, including large tumor burden, hypercalcemia, liver or kidney dysfunction, and substantial immunodeficiency resulting in frequent infectious complications.^{33,37,309} Importantly, as well, ATLL cells possess intrinsic chemoresistance resulting from elevated expression of the multidrug resistance gene²⁸⁵ and mutations in the *p53* gene.⁴⁶⁶ Complete remission in ATLL is defined by normalization of the complete blood count and resolution of all tumor masses, lasting for at least 1 month,³⁷ although patients with these factors but maintaining fewer than 5% atypical lymphocytes are also considered to be in complete remission because this situation may be noted in HTLV-1 carriers without malignant disease (“pre-ATL,” which may either disappear or progress to clinical ATLL).^{37,569}

Given ATLL’s intrinsic chemotherapy resistance, alternative treatment approaches have been explored. Antiviral therapy is an important aspect of ATLL treatment,^{31,33,211,259,331,560} especially for acute ATLL,^{34,37,216,263,338,339,571} and even more so for acute ATLL that has not been previously treated.⁵⁷¹ By a mechanism that remains unclear, treatment with AZT and interferon- α (IFN- α) has proved to increase survival rates in both chronic and acute forms of ATLL.^{35,322} As well, it was recently reported that IFN- α induces a gene expression suppressive effect inducing an arrest of cell cycle in infected cells; by adding AZT, an added effect is observed wherein *p53* is induced and cell apoptosis takes place.²⁶⁷ Previous reports of AZT effect were similar, showing inhibition of telomerase activity along with stabilization and reactivation of *p53*, *p21*, and *p27*, resulting in the induction of cell apoptosis.¹¹⁴ The combination of IFN and arsenic has also been shown to cause cell apoptosis mediated by Tax degradation and has also been proposed as an alternative therapy.^{112,311} A meta-analysis of ATL survival since 1995 compared different treatment strategies for ATLL—antiviral therapy alone, chemotherapy alone, and chemotherapy followed by maintenance antiviral therapy. The 5-year overall survival rates were 46% for 75 patients who received first-line antiviral therapy, 20% for 77 patients who received first-line chemotherapy, and 12% for patients who received first-line chemotherapy followed by antiviral therapy.³⁴ Patients with acute, chronic, and smoldering ATLL substantially benefitted from first-line antiviral therapy, and ATLL lymphoma patients did better with chemotherapy.³⁷ Acute ATLL patients achieved a 5-year survival rate of 28%, in contrast to

TABLE 192A.3 Clinical Findings in Adult T-Cell Leukemia/Lymphoma

Median age of onset	40–60 y
Gender	Caribbean, Africa: Females > males Japan: Males slightly > females (1.4 : 1)
Clinical and Laboratory Findings	
Generalized lymphadenopathy (%)	50–80
Hepatosplenomegaly (%)	25–67
Skin involvement (%)	40–60
Elevated white blood cell count (%)	60–66
Hypercalcemia (%)	32–63
Pulmonary involvement (%)	14
Lytic bone lesions (%)	2–10
Central nervous system involvement (%)	2–10

the 10% 5-year survival rate with chemotherapy with or without maintenance antiviral therapy.³⁷ Achievement of complete remission with antiviral therapy was important, with 82% of this subgroup surviving at 5 years.³⁷ Antiviral therapy resulted in 100% 5-year survival in chronic and smoldering forms, yet in ATLL lymphoma a survival disadvantage (median survival time of 7 months; 5-year survival of 0) was seen compared with first-line chemotherapy with or without maintenance antiviral therapy.³⁴ Other antiretroviral agents, including lamivudine (3TC), have been evaluated in ATLL, but without benefit being shown.³⁷

Standard therapy for acute ATLL is now AZT/IFN, with patients possessing wild-type *p53* at substantial survival benefit over those with mutated *p53*.¹¹³ Long-term therapy is required because relapse will occur if treatment is stopped, and eventually, even though survival is prolonged, patients with acute ATLL usually relapse eventually and die.³⁷ For young patients with acute ATLL and a matched donor, allo-hematopoietic stem cell transplantation (allo-HSCT) is recommended.³⁷

Arsenic trioxide synergizes with IFN to induce cell cycle arrest and apoptosis in HTLV-1-infected ATLL leukemia cells,³² eradicating leukemia-initiating cell activity.¹⁴³ Trials are currently ongoing to assess the role of arsenic/IFN as consolidation therapy for patients achieving satisfactory responses to induction therapy.³⁷ Particularly with chronic and smoldering subtypes, suggestions have been made that arsenic may have a role in achieving cure by eliminating leukemia-initiating cell,^{32,143} and arsenic/IFN maintenance therapy is being investigated in acute ATLL as well.³⁷

Several other therapies are accepted as second- and subsequent-line treatments for ATLL, including multiagent chemotherapy, allo-HSCT, and newer agents, such as purine analogs, histone deacetylase inhibitors, and monoclonal antibodies.^{533,534}

Different chemotherapy combinations and regimens have been investigated over the years,³⁷ particularly in Japan, where ATLL is common and the resources to intensively address it exist, unlike in most HTLV-1–endemic settings. First- and second-generation Japanese protocols with the regimen of cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (CHOP) and other combined chemotherapies obtained complete remission of up to 42%, but with early relapses and 4-year survival rates of less than 10% for aggressive subtypes.³⁷ Similar results were seen historically from outside Japan.⁴⁵³ Intensive induction therapy supported by granulocyte colony-stimulating factor yielded complete remission rates as high as 67% for lymphoma subtype, but still poor long-term survival.⁵⁸⁶ Newer cytotoxic agents, including deoxycoformycin (a nucleoside analog),^{533,534} irinotecan (a topoisomerase I inhibitor),⁵³² and MST-16 (a topoisomerase II inhibitor), have been studied in relapsed ATLL patients,⁵¹³ but with poor outcomes, as with earlier chemotherapy approaches.³⁷

In Japan, allo-HSCT has improved ATLL prognosis, with several studies showing that discontinuation of immunosuppressant therapy induces sustained remission in substantial numbers of posttransplantation relapsed patients, suggesting that ATLL may be susceptible to a graft-versus-leukemia effect.²⁵¹ In a large Japanese review, outcomes were evaluated for 386 patients who had undergone allo-HSCT.²²⁵ At a median follow-up of 41 months, 3-year overall survival was 33%.²²⁵ Donor lymphocyte infusions have been used in Japan for relapse after allo-HSCT, with sustained complete remission of more than 8 years in case reports.²⁵¹ Allo-HSCT, while promising in some cases, has limited utility for ATLL presenters as a whole, given limits to eligibility for allo-HSCT based on severe immunosuppression at presentation, older age, and poor overall health status.³⁷ Especially in acute ATLL, complete remission remains low even with allo-HSCT.³⁷

Noting ATLL cells' ubiquitous surface expression of IL-2 receptors, monoclonal antibodies against the IL-2 receptor have been used in trial in patients with relapsed or refractory ATLL.^{37,109} Good responses are uncommon.³⁷ Case reports indicate some initial success with alemtuzumab anti-CD52 antibody, but duration of response is short and substantial risk for opportunistic infections exists, especially cytomegalovirus reactivation.^{351,447} Helper T cell type 2 and regulatory T cells express CC chemokine receptor 4 (CCR4), and a next-generation humanized anti-CCR4 antibody, KW-0761, has demonstrated possible benefit versus relapsed ATLL expressing the CCR4 phenotype.⁵⁹² In chronic and smoldering ATLL subtypes, monoclonal antibodies can be

used as single agents, although clinical trials of monoclonal antibodies with chemotherapy in the lymphoma subtype and ART in the acute subtype are needed to better define their ultimate utility in treating ATLL.³⁷

Supportive therapy is necessary in managing ATLL, including treatment of hypercalcemia and prophylaxis against *Pneumocystis jiroveci* pneumonia, viral infections, and fungal infections.⁵³⁵ In patients with potential past or present *Strongyloides* exposure, prophylaxis with ivermectin or albendazole should be given.³⁷ Patients with aggressive ATLL should be considered for intrathecal prophylaxis because more than half of relapses at new sites after chemotherapy are in the CNS.³⁷

Other malignant diseases have been associated with HTLV-1 infection, although the supporting evidence for these associations is less clear than that for ATLL. Cutaneous T-cell lymphomas, such as mycosis fungoides and Sézary syndrome, have been described in adults and a child with HTLV-1 infection.^{36,204,565,599} In one small study of eight patients with Sézary syndrome, HTLV-1 mRNA expression was found in four patients,¹⁸³ and HTLV-1–like sequences have been found in patients with mycosis fungoides.⁶⁴ Multiple myeloma, B-cell chronic lymphocytic leukemia,²⁶ acute lymphoblastic leukemia (ALL), and acute myeloid leukemia (AML) also have been described in patients infected with HTLV-1.²⁶ These malignancies may arise as a result of chronic antigenic stimulation of B cells by HTLV-1–infected T cells, with such stimulation leading to uncontrolled B-cell expansion. In the Caribbean and Chile, HTLV-1 has been associated with the development of T-cell non-Hodgkin lymphoma.^{26,317} Although some cases of adult HTLV-1–associated lymphomas are similar in character to anaplastic large cell lymphoma (ALCL), in a series of 33 cases of pediatric ALCL from Brazil, where HTLV-1 is endemic, no cases demonstrated proviral HTLV-1 DNA, suggesting no relationship between HTLV-1 and ALCL in children.¹⁹⁹ A case of primary brain T-cell lymphoma in a young HTLV-1–positive adult has been reported,³⁰⁰ as has a case of small cell cancer of the lung with monoclonally integrated HTLV-1. A pulmonary infiltrative syndrome resembling lymphoid pulmonary hyperplasia seen in HIV-1–infected children has been reported in patients with HTLV-1–associated myelopathy.⁴⁹⁷

Human T-Cell Lymphotropic Virus Type 1–Associated Myelopathy

In the 1880s, a “multiple neuritis” syndrome with a predominantly ataxic motor neuropathy was reported in Jamaica. In subsequent years, similar syndromes of unknown origin were described in other geographic locales and given different names, including Strachan disease, central neuritis, Jamaican neuropathy, tropical spastic paraplegia, and tropical spastic paraparesis.⁶⁰⁰ The identification of HTLV-1 in 1980, the development of antibody tests to diagnose HTLV-1 infection, and the recognition that HTLV-1 and TSP were endemic in the same geographic locations led to the hypothesis that these entities could be associated. In 1985, Gessain and colleagues¹⁷⁸ performed a case-control study in Martinique in which patients with TSP of unknown cause were compared with a control group of nurses and blood donors without neurologic disease. Sixty percent of the patients with TSP versus only 4% of controls had HTLV-1 serum antibodies detected.^{161,178} In the same year, a report was published on the detection of HTLV-1 antibodies in the cerebrospinal fluid (CSF) and serum of individuals afflicted with TSP.⁴⁵⁶ In 1986, a series of Japanese patients with a similar clinical syndrome who also had HTLV-1 antibodies in their CSF were described, and these investigators proposed that the syndrome be called *HTLV-1–associated myelopathy*.⁴⁰² At a 1988 meeting of the World Health Organization (WHO) Scientific Group on HTLV-1 Infections and Its Associated Disease, researchers proposed that HAM and HTLV-1–associated TSP were clinically and pathologically identical and recommended that the disorder be known by the acronym *HAM/TSP*.^{582,583}

Diagnostic criteria developed at this meeting, and revised in 1989, base diagnoses of HAM/TSP on the presence of a variety of clinical and laboratory criteria,¹⁹⁶ including anti-HTLV-1 antibodies in serum and CSF.^{59,439} With advances in diagnostic technology, particularly molecular techniques and HTLV-1 proviral load testing, in 2006 De Castro-Costa and colleagues proposed simplified diagnostic criteria for HAM/TSP that may allow diagnosis at earlier stages, when treatment may be more successful. Widely adopted in Brazil, the De Castro-Costa

criteria¹¹⁶ use myelopathic symptoms, serologic findings or detection of HTLV-1 DNA, the exclusion of other disorders, and the results of HTLV-1 proviral load testing to ascertain one of three categories of HAM/TSP: possible, probable, or definite. HTLV-1 proviral load progressively increases by De Castro-Costa ascertainment category,^{13,196} with a level higher than 50,000 HTLV-1 copies/10⁶ peripheral blood mononuclear cells (PBMCs) an additional criterion for differentiating definite from probable HAM/TSP cases (Box 192A.2).¹⁹⁶

The disease usually occurs in HTLV-1–endemic areas, including the Caribbean, southern Japan, equatorial Africa, Central and South America, Melanesia, and southern Africa. Sporadic cases have been described in nonendemic areas, usually in immigrants from endemic areas or their sexual contacts or in recipients of blood transfusions (before the advent of HTLV blood screening). Incidence and prevalence estimates suggest that between 0.3% and 3% of asymptomatic carriers will develop HAM/TSP,¹⁹⁵ and women are more commonly affected than men.³¹⁴ Yet clinically recognized and diagnosed HAM/TSP is likely the tip of a neurologic iceberg in HTLV-1; a recent cohort study demonstrated that up to 30% of asymptomatic carriers presenting with mild neurologic symptoms did not fulfill HAM/TSP criteria.⁵¹⁴

As with ATLL, the chief risk factor for developing HAM/TSP is a high HTLV-1 proviral load. Yet genetic factors appear to play a role as well, with gene polymorphisms, such as for IL28B, associated

with disease development²⁰; that cases aggregate in families has long been recognized.³⁸⁸

Case rates differ geographically. In HTLV-1–seropositive persons in Japan, the incidence of HAM/TSP is 3.1 per 100,000 HTLV-1–infected persons per year. In contrast, the annual incidence of HAM/TSP in HTLV-1–infected persons in Jamaica and Trinidad was 22.1 per 100,000 persons.³¹⁴ This difference in incidence is hypothesized to reflect an association between the time that HTLV-1 infection is acquired and the type of disease manifestation that occurs. In the Caribbean, most HTLV-1 infection being acquired sexually during adult life is more common than in Japan, and HAM/TSP is the most common clinical manifestation of the disease. In Japan, sexual transmission is less common, most infection is acquired by maternal-to-child transmission during infancy, and ATLL is the most common disease manifestation. Case reports of HAM/TSP occurring after receipt of blood transfusions and the finding in Japan and Martinique that 13% to 20% of patients with HAM/TSP had a history of receiving blood transfusions accelerated the decision of blood banks in the United States to screen for HTLV-1 antibodies. In Japan, a 16% decrease in the number of HAM/TSP cases occurred in the 2 years after initiation of blood screening.^{170,171,401}

Although the mean onset of disease is in the fourth decade of life, incubation of this disease appears to be shorter than that of ATLL. In patients with HTLV-1 infection acquired by transfusion in whom HAM/TSP subsequently developed, the median time to development of symptoms after receiving a transfusion was 3.3 years, and in one report, HAM/TSP occurred 18 weeks after blood transfusion.^{194,401} Onset of symptoms is uncommon in persons younger than 20 years or older than 70 years, and incidence increases from age 20 years through age 50 years and then declines.¹⁸⁹ However, HAM/TSP has been reported in children and adolescents, and the majority of cases are from Brazil,^{59,121,205,439,443} with a predominance in girls.⁵⁹ Most pediatric and adolescent cases have been in vertically infected children,^{205,439} although HAM/TSP has been described in a 6-year-old child after transfusion-acquired HTLV-1 infection.⁴⁰¹ Most HAM/TSP cases in children and adolescents occur in patients with active, or a history of, HTLV-1–associated infective dermatitis.⁴³⁹ In one study from Brazil, 60% of pediatric and adolescent infective dermatitis cases had neurologic symptoms, and one-third had frank HAM/TSP.^{59,439}

Clinical features of HAM/TSP in children and adolescents are similar to those in adults,⁵⁹ and it typically presents as a slowly progressive neurologic disease¹⁸⁰ involving the pyramidal tracts and including chronic progressive spastic paraparesis and weakness of the limbs, particularly the legs, that results in an insidious onset of gait disturbance (see Table 192A.5). Mild sensory loss and painful paresthesias may develop and result in complaints of extremity numbness or dysesthesia and low back pain. Vesical dysfunction generally presents later in the illness but is particularly characteristic of pediatric disease and is characterized by urinary urgency, difficulty emptying the bladder, and incontinence.⁴³⁹ Urodynamic studies are important in children for diagnosis as well as for follow-up treatment of vesical dysfunction.⁵⁹ Bowel issues in adults include constipation and incontinence. Erectile dysfunction may be seen. Neurologic examination shows hyperactive deep tendon reflexes, clonus, extensor plantar reflexes, proximal muscle wasting, and a spastic paraparesis with a slow, scissoring gait; mild sensory changes may be observed. Cognitive function and the cranial nerves usually are spared. Systemic nonneurologic symptoms suggestive of an autoimmune process, such as pulmonary alveolitis, uveitis, arthropathy, Sjögren syndrome, and vasculitis, also may be noted.^{230,233,498} Progression is variable, but, on the whole, prognosis is poor, with complete motor disability of the lower extremities in half of patients 10 years after onset, whereas 30% of patients become bedridden.^{181,186}

In endemic areas, patients, particularly children and adolescents, without previously known HTLV-1 infection, with symptoms of myelopathy should be serologically screened for HTLV-1.^{59,439} Even when HTLV-1 infection status is known, the differential diagnosis of the symptoms described earlier is broad. Of particular importance are CSF studies to rule out other infectious diseases that may involve the spinal cord, including tuberculosis, syphilis, and toxoplasmosis, and, in at-risk geographic areas, cysticercosis and schistosomiasis.⁴³⁹

BOX 192A.2 Diagnostic Criteria for Human T-Cell Lymphotropic Virus Type 1–Associated Myelopathy/Tropical Spastic Paraparesis: Levels of Ascertainment

Definite

1. A nonremitting progressive spastic paraparesis with sufficiently impaired gait to be perceived by the patient. Sensory symptoms or signs may or may not be present. When present, they remain subtle and without a clear-cut sensory level. Anal and urinary sphincter signs and symptoms may or may not be present.
2. Presence of HTLV-1 antibodies in serum and CSF confirmed by Western blot and/or a positive PCR for HTLV-1 in blood and/or CSF.
3. Exclusion of other disorders that can mimic HAM/TSP.^a

Probable

1. Monosymptomatic presentation: Spasticity or hyperreflexia in the lower limbs or isolated Babinski sign with or without subtle sensory signs or symptoms, or neurogenic bladder only confirmed by urodynamic testing.
2. Presence of HTLV-1 antibodies in serum and/or CSF confirmed by Western blot and/or a positive PCR for HTLV-1 in blood and/or CSF.
3. Exclusion of other disorders that can mimic HAM/TSP.^a

Possible

1. Complete or incomplete clinical presentation.
2. Presence of HTLV-1 antibodies in serum and/or CSF confirmed by Western blot and/or a positive PCR for HTLV-1 in blood and/or CSF.
3. Disorders that can mimic HAM/TSP have not been excluded.^a

^aThe following conditions should be excluded by appropriate laboratory and clinical evaluation to minimize risk for misdiagnosis of HAM/TSP: multiple sclerosis; carcinomatous meningitis; familial spastic paraparesis; transverse myelitis; primary lateral sclerosis; paraneoplastic syndromes; syringomyelia; Lyme disease; vitamin B₁₂ and folate deficiency; Behçet disease; neurosyphilis; neurotuberculosis; sarcoidosis; HIV vacuolar myelopathy; collagen vascular diseases; autoimmune myelopathies; Sjögren syndrome; toxic myelopathies; amyotrophic lateral sclerosis; fungal myelopathy; spinal arteriovenous fistula; hepatic myelopathy; parasitic myelopathy (visceral larva migrans of *Toxocara canis* and *Ascaris suum*); spinal cord compression (e.g., spinal tumor, cervical spondylosis, brain parasagittal tumor); endemic regional myelopathies with similar clinical manifestations (including schistosomiasis and neurocysticercosis).

CSF, Cerebrospinal fluid; HAM/TSP, HTLV-1–associated myelopathy/tropical spastic paraparesis; HTLV, human T-cell lymphotropic virus; PCR, polymerase chain reaction. Modified from De Castro-Costa CM, Araujo AQ, Barreto MM, et al. Proposal for diagnostic criteria of tropical spastic paraparesis/HTLV-1-associated myelopathy (TSP/HAM). *AIDS Res Hum Retroviruses*. 2006;22:931-935.

Helminthic coinfections are common in HTLV-1-infected persons,^{432,433,502} including helminths other than *Strongyloides*, such as *Ascaris* and *Schistosoma* spp.⁵⁰² HTLV-1 infection is associated with a high Th1 response, although helminthic infections have been shown in some studies to downregulate Th1 responses and attenuate chronic inflammatory diseases.^{76,341,407} It has been suggested that treatment of helminths in HTLV-1-infected persons may raise the risk for subsequent development of HAM/TSP, yet data to date suggest that treatment of helminthic coinfections do not affect the risk for developing neurologic disease in HTLV-1 infection or otherwise adversely affect HTLV-1-infected persons.⁵⁰²

The pediatric form of HAM/TSP has been associated with multiple comorbidities, including short stature, hypocalcemia, and increases in urinary phosphorus and cyclic adenosine monophosphate after parathyroid hormone administration, raising the question of whether HTLV-1 may induce pseudohypoparathyroidism (PHP) in some children.⁵⁹⁷ Current thinking is that HTLV-1 does not induce PHP, rather PHP may be a risk factor for developing HAM/TSP in HTLV-1 carriers.³⁰⁴ Unlike in most adult cases, in which progression is insidious, pediatric HAM/TSP is generally rapidly progressive, in some cases with substantial disability within weeks to months of first symptoms.⁴³⁹ Some adult populations, such as persons older than 60 years acquiring HTLV-1 through blood transfusion, are more likely to experience rapid progression.²⁹⁷ Subacute HAM/TSP progression (requiring wheelchair use during first 2 years of symptoms²⁹⁷) is also uncommon (<10% of cases), with almost all cases in women, most of whom acquired their HTLV-1 infection through sexual contact.²⁹⁷ Both rapidly progressive and subacute HAM/TSP may be more amenable to improvements with aggressive immunosuppressive treatment, and attempts to risk-stratify HAM/TSP presentations for projected chronicity of symptoms have been made.²⁹⁷ Studies to date have not shown an association between HTLV-1 proviral load and risk for more rapid progression, suggesting that factors other than proviral load are involved in this determination.²⁹⁷

Nonspecific lesions of the brain are observed with magnetic resonance imaging (MRI) in as many as 75% of patients, but no clear correlation has been established between the lesions and symptoms. Atrophy of the spinal cord may occur, usually in the thoracic region, as may discrete lesions visible on MRI.²⁹⁷ Multiple foci of increased T2 signal intensity are found in the periventricular white matter, similar to the findings observed in patients with multiple sclerosis. However, cognitive impairment may be noted in multiple sclerosis but is not found in HAM/TSP, and HTLV-1 sequences have not been detected in the peripheral blood or CNS of patients with multiple sclerosis.³⁹⁷

High HTLV-1 antibody levels are found in both peripheral blood and CSF. In CSF, mild to moderate pleocytosis, increased protein, oligoclonal immunoglobulin bands, or any combination of these findings may be observed. Elevated CSF neopterin, an indicator of cellular immune activation, may be present, and its CSF concentration correlates with disease severity.⁴⁶⁴ In approximately 50% of patients, atypical flower lymphocytes are observed and account for approximately 1% to 15% of peripheral blood lymphocytes; these cells also may be seen in CSF.²³³ Unlike the monoclonal integration observed in ATLL, polyclonal integration of HTLV-1 is noted in cells from patients with HAM/TSP.

Pathologically, HAM/TSP is characterized by perivascular demyelination and neuronal lesions. Macroscopic atrophy of the spinal cord occurs, with changes consistent with a chronic inflammatory process characterized by perivascular cuffing of mononuclear cells and lymphocytic infiltration of the brain and spinal cord. Early in the disease, these lymphocytes consist of both CD8⁺ and CD4⁺ T cells, along with B lymphocytes and macrophages in areas of parenchymal damage.²⁴³ HTLV-1 proviral DNA can be demonstrated in CD4⁺ cells in the infiltrates by in situ PCR. Evidence suggests that these HTLV-1-infected CD4⁺ cells migrate from the peripheral blood and cross the blood-brain barrier to enter the nervous system.^{13,88} Later in the disease process, the inflammatory cells are fewer in number and consist primarily of CD8⁺ cytotoxic T cells.¹³ Marked myelin and axonal destruction and astrocytic gliosis are prominent. The lower thoracic spinal cord is particularly affected, and parenchymal damage of both white and gray matter of the cord may be present. In the brain, although perivascular mononuclear cell infiltration may be seen, parenchymal damage is an unusual finding.

However, rare patients may have white-matter lesions, cerebellar symptoms, amyotrophic lateral sclerosis-like symptoms, or neuropathy.²³³

The pathogenesis of HAM/TSP is not fully understood, but it is believed to be related to a high HTLV-1 provirus burden and an exaggerated proinflammatory cellular immune response,^{13,563} with the risk for HAM/TSP increasing exponentially as proviral load exceeds 10,000/10⁶ peripheral blood mononuclear cells.¹³ In a large Brazilian cohort, a proviral load cutoff of 11,400/10⁶ has a 78.2% sensitivity for identifying HAM/TSP diagnoses over a 14-year follow-up.¹⁶⁴ When compared with asymptomatic HTLV-1-seropositive individuals or those with ATLL, patients with HAM/TSP have higher HTLV-1 antibody titers, a higher proviral load, and elevated levels of spontaneous lymphocyte proliferation and proinflammatory cytokines, including IL-1, IFN- α , and TFN- α .^{318,373,374}

One postulated mechanism for nervous system damage is direct infection of CNS glial cells by HTLV-1; a direct cytotoxic immune response to the glial cell is generated and results in demyelination.²³⁰ However, HTLV-1 expression appears to be localized to infiltrating CD4⁺ lymphocytes within the spinal cord lesions rather than nervous system parenchymal cells, and no clear evidence has established that HTLV-1 infects CNS cells.³⁷⁵ Alternatively, the heightened HTLV-1-specific immune response in patients with HAM/TSP and neuropathologic findings suggests that immune-mediated mechanisms may have a role in the pathogenesis of disease.²⁸⁷

Tax has a role in inducing HAM/TSP.⁴⁶⁴ HTLV-1 *tax* mRNA expression is significantly higher in HAM/TSP patients than in asymptomatic HTLV-1 carriers, and this correlates with HTLV-1 proviral load, Tax-specific CD8⁺ T-cell frequency, and disease severity.^{177,593} Mononuclear cells infiltrating the spinal cord overexpress several cytokines, chemokines, and matrix metalloproteinases (MMPs) that are transactivated by Tax protein^{121,464} and that may induce demyelination, as well as increase the transmigration of additional HTLV-1-infected lymphocytes to the inflammatory lesion.^{230,373,374} These include TNF- α ,⁵⁴³ monocyte chemoattractant protein-1 (MCP-1),⁵⁴⁴ and MMP-9. Expression of the *HBZ* gene also correlates with CSF neopterin concentration and disease severity, as well as decreases after successful immunomodulatory treatment for HAM/TSP, suggesting a role for *HBZ* in HAM/TSP pathogenesis.⁴⁶⁴ HTLV-1-specific CD8⁺ cytotoxic T cells can be found in the CSF and in the peripheral blood of patients with HAM/TSP, and a significant reduction in the naïve T-cell population occurs with a concomitant increase in the memory/effector CD8⁺ cell population.^{244,245,373} Examination of the T-cell receptor repertoire shows significant expansion of the CD8⁺ T-cell population in patients with HAM/TSP as opposed to asymptomatic carriers. Many of these CD8⁺ cells correspond to cytotoxic T lymphocytes directed against epitopes of the immunodominant Tax protein of HTLV-1.⁵⁴⁵

Specific characteristics of the virus also may influence disease manifestations. In one study, a specific *tax* gene phylogenetic subgroup, *tax A*, was found to occur more commonly in patients with HAM/TSP than in healthy HTLV-1 carriers, suggesting that functional or immunogenic differences in the transactivating Tax protein among HTLV-1 viral types may play a role in causing disease.¹⁶⁵ Another hypothesized mechanism is more indirect and involves an HTLV-1-associated activation of autoreactive cells that could lead to an autoimmune process inducing myelin destruction. The finding that numerous autoimmune-like diseases may occur in HTLV-1-infected patients and may coexist with HAM/TSP is consistent with the latter hypothesis.²³³

Despite extensive effort over the more than 35 years since its definition, HAM/TSP still has no specific treatment,³³⁰ and current approaches do not affect the natural history of HAM/TSP.^{184,330} Mean survival after the onset of symptoms is 10 years, although prolonged survival may be seen, and the major causes of death are infection and cancer.⁵⁴¹ Many strategies, including corticosteroids, IFN- α and IFN- β , danazol, pentoxifylline, tamibarotene,¹⁴⁵ and plasmapheresis, have had their efficacy evaluated, yet none of these has shown an effect on long-term prognosis and there is not, currently, enough evidence to inform recommendations on a standard treatment.³⁹²

Case reports suggest that, particularly in early phases of HAM/TSP when substantial parenchymal inflammation is present, responses to such therapies are more likely, whereas later in the disease course,

degeneration of the white matter and glio-mesenchymal tissue reactions dampen the odds for success.²⁹⁷ In Brazilian pediatric cases treated with intravenous methylprednisolone early in disease course, vesical status improved in most cases, but motor responses were generally poor.⁴⁴⁰ In most reports, corticosteroids and IFN treatments are of only transient benefit and often associated with serious side effects.³³⁰ Patients with HAM/TSP, particularly children and adolescents, are often highly affected by the psychological and social aspects of disability, and care is best provided by a multidisciplinary team including a psychologist, physical and occupational therapists, physicians, and nurses.⁵⁹ Depression and anxiety substantial enough to require specific treatment are common.¹⁷³ Symptomatic treatments with agents such as baclofen and anticonvulsants to relieve spasticity and neuropathic pain are of benefit in many patients,⁵⁹ as are oxybutynin for urinary incontinence and bethanechol for urinary retention, along with high doses of vitamin C (2 g/day) to acidify the urine and daily oral nitrofurantoin when recurrent urinary tract infection is an issue.¹³ Valproic acid may prove dually useful, for both symptoms and disease activity, because it induces reductions in proviral load by activating viral gene expression and exposing HTLV-1–infected cells to the immune system.²⁹⁴

Several studies have evaluated antiretrovirals in the treatment of HAM/TSP, with and without myelopathy.⁵¹⁸ Specifically evaluated have been AZT, 3TC, and raltegravir, with different but consistently poor results.⁵¹⁸ This may not be surprising, considering the limited role intracellular viral replication plays in HTLV-1–associated disease compared with division of infected cells yielding high proviral levels. With its favorable safety profile, raltegravir has been proposed as an option for individuals with high HTLV-1 proviral loads to treat early or reduce the rate of development of HTLV-1–associated conditions⁵³⁰; a clinical trial initiated in 2013 evaluating this is ongoing.⁴⁴⁴

Given the implication of activated T cells and mononuclear phagocytes, along with their associated cytokines, in the pathogenesis of HAM/TSP, there is interest in assessing whether inhibition of T-cell and/or mononuclear phagocyte activation is of benefit in patients with early or clinically progressing HAM/TSP.³³⁰ An open-label, proof-of-concept, 48-week pilot study enrolled onto cyclosporine A (an immunosuppressive inhibitor of activated T cells) therapy seven patients older than 16 years with early (<2 years) or progressive (>50% deterioration in timed walk during the preceding 3 months) HAM/TSP.³³⁰ Five of the seven patients showed objective clinical improvement after 3 months of treatment with cyclosporine A, and the two who did not show improvement experienced clinical deterioration and stopped therapy.³³⁰ Overall pain, mobility, spasticity, and bladder function improved by 48 weeks, and larger, randomized controlled studies are planned.³³⁰ Minocycline is known to inhibit activated mononuclear phagocytes,¹⁴⁶ and recent *in vitro* work has shown minocycline's ability to inhibit TNF- α and IL-1 β expression in cultured CD14⁺ cells of patients with HAM/TSP, while also inhibiting IFN- γ expression in CD8⁺ T cells of patients with HAM/TSP, and suggesting that minocycline may offer a novel treatment strategy directed at suppression of CD8⁺ T-cell activation in patients with HAM/TSP and other HTLV-1–associated neurologic disease.¹⁴⁶

Human T-Cell Lymphotropic Virus Type 1–Associated Uveitis

Defined as uveitis of unknown etiology in an HTLV-1–infected individual, HTLV-1 uveitis was first described in Japan in 1992 based on studies showing higher incidence of HTLV-1 seropositivity in individuals with uveitis of unknown etiology compared with to uveitis of known etiology.⁷² In HTLV-1–endemic areas in Japan, 38% of patients with idiopathic uveitis were infected with HTLV-1, in contrast to 19% of patients with nonuveitic ocular disease and 10% with uveitis of known origin.³⁴⁹ In the younger age group (20–49 years) with idiopathic uveitis, HTLV-1 seroprevalence was 49%. Similarly, in Brazil, an area of lower HTLV-1 endemicity, HTLV-1 seroprevalence was elevated in patients with idiopathic uveitis; 1.8% of patients with idiopathic uveitis were HTLV-1–seropositive versus none of those with uveitis of known origin.⁵⁹¹ Along with epidemiologic associations, the causality of HTLV-1 in HTLV-1 uveitis was suggested. HTLV-1 antibody was detected in the aqueous humor of patients with HTLV-1 uveitis,³⁴⁹ as was the presence of HTLV-1 virus itself and HTLV-1–infected cells in ocular fluid from HTLV-1 uveitis cases,³⁴⁷ including more than 50% of Japanese patients with

HTLV-1 uveitis. In Japan, HTLV-1 uveitis prevalence in the general population is 0.112%⁵⁰⁸; in a survey of 105 asymptomatic Brazilian HTLV-1 carriers, uveitis was found in 2.8% of infected persons. Women are almost twice as likely to be affected as men in Japan, yet mean age of onset is earlier in men (34.8 years vs. 48.1 years).³⁷⁷ As noted for HAM/TSP, genetic factors also may be associated with a susceptibility to, or the severity of, HTLV-1–associated uveitis.⁴⁷⁸

HTLV-1 uveitis is likely the result of HTLV-1–infected T cells infiltrating the eye and producing inflammatory cytokines.^{345,349,463,478} The long-term follow-up of Japanese patients informs HTLV-1 uveitis presentation and clinical course.³⁷⁷ Clinically, HTLV-1 uveitis presents as an acute, moderate to severe vitreitis, along with mild iritis and mild retinal vasculitis, in what typically are healthy, asymptomatic HTLV-1 carriers.^{72,346,348,376,485} Uveitis is unilateral in 60% of cases, with blurred vision and floaters the most common symptoms. Onset is typically abrupt. Characteristic findings on examination are mild anterior segment inflammation, nongranulomatous in more than 80% of cases, as well as vitreitis with fine granular and lacework-like membranous vitreous opacities. Retinal vasculitis, exudative retinal lesions, and optic disc abnormalities are common, occurring in 60%, 25%, and 20% of cases, respectively. HTLV-1 uveitis anatomic characterization is intermediate in more than 75% of cases. Five percent of HTLV-1 uveitis cases have iritis alone.³⁴⁹ The uveitis is generally mild to moderate, and visual acuity is only mildly affected in most patients. The disease usually responds to topical, periocular, or systemic steroids, with complete resolution in 4 to 8 weeks, although recurrence is seen in 40% to 50% of cases after steroid therapy is discontinued.^{349,376} Approximately 33% of cases are associated with complications, including cataract, glaucoma, epiretinal membranes, persistent vitreous opacities, retinochoroidal degeneration, retinal vascular occlusion, and optic atrophy,^{72,197} and poor visual outcomes may be seen in 4% to 10% of cases.⁷² Clinical studies suggest that retinal vasculitis unresponsive to corticosteroid therapy may be a poor prognostic sign.³⁷⁷ In Japanese patients, 15% to 20% are diagnosed with Graves disease before onset of HTLV-1 uveitis, and approximately 7% have concomitant HAM/TSP before or after onset of HTLV-1 uveitis.^{72,197} A study of the association between Graves disease and HTLV-1 uveitis found that methimazole was administered in all cases before HTLV-1 uveitis onset.⁴⁶⁸ ATLL has not been associated with HTLV-1 uveitis, although rare cases of ATLL can present with ocular findings that mimic severe HTLV-1 uveitis, principally a necrotizing retinal vasculitis.²⁹¹ A study of 105 asymptomatic Brazilian HTLV-1–seropositive adults found abnormal results in at least one lacrimal film evaluation test in 40% versus 23% of uninfected controls,⁵⁹¹ a finding suggesting that abnormal early ocular abnormalities may be present in asymptomatic HTLV-1 carriers.

Non-Japanese HTLV-1 uveitis cases may be associated with findings not typically described in Japan, such as corneal pathology in Brazilian patients and patients from the Caribbean.⁷² HTLV-1 uveitis in children and adolescents is rare, with cases reported as young as 3 years; girls more commonly affected than boys; and presenting symptoms and ocular examination findings similar to those in adults.^{258,266} As in adults, topical or systemic steroids are usually effective in pediatric HTLV-1 uveitis cases, and topical steroids may need to be continued as maintenance therapy to prevent relapses.²⁶⁶ As in adults, the presence of retinal vasculitis predicts long-term visual compromise, usually with slow progression poorly responsive to corticosteroids and resulting in diffuse chorioretinal degeneration.⁵⁹

Pediatric Manifestations

Infective dermatitis. A chronic recurrent eczema of childhood called *infective dermatitis* was first described in 1966 as a series of 17 cases in Jamaican children.⁵⁰³ These cases were reported as presenting with severe, infected lesions involving the ears, face, scalp, shoulders, and neck, with onset of illness at approximately 2 years of age and rarely before 18 months of age.^{122,503} In 1967, researchers observed that cultures of the nares or skin lesions in children with infective dermatitis often were positive for *Staphylococcus aureus* or β -hemolytic streptococci.⁵⁶⁶ It is now recognized that infective dermatitis is always associated with either or both of these organisms, typically with nonvirulent strains.⁵⁶ Patients with these infections responded well to antibiotic therapy but relapsed

after therapy was withdrawn. The refractory nature of the disorder with frequent exacerbations, infections with bacteria that usually were nonviral, and resistance to treatment suggested an association with immune dysfunction. After HTLV-1 was identified in 1980, epidemiologic studies demonstrated that HTLV-1 was endemic in Jamaica. Because HTLV-1 infection was known to be associated with immune dysfunction and enhanced susceptibility to infections,³²⁹ an association between infective dermatitis and HTLV-1 infection was hypothesized. Approximately 10% of childhood eczema cases in Jamaica are infective dermatitis,^{276,278} and the probability of developing infective dermatitis in Jamaican children after perinatal HTLV-1 infection is estimated at 2%.³¹⁵

In 1990, La Grenade and colleagues^{274,275} first linked infective dermatitis to HTLV-1 infection in Jamaican children, after observing that of 14 children with typical infective dermatitis and 11 with atopic dermatitis, all children with infective dermatitis were HTLV-1 seropositive compared with none of those with atopic dermatitis. A subsequent report described 50 children with infective dermatitis, all of whom were HTLV-1 seropositive, as opposed to only 14% of 35 children with atopic dermatitis.²⁷¹ Subsequently, cases of infective dermatitis were reported in HTLV-1-infected children in Brazil,^{56,122,398} Trinidad and Tobago,⁴⁹⁹ French Guiana,³⁷⁹ Colombia, Peru,¹² Senegal,¹² and Japan.^{62,536} In Japan, however, infective dermatitis is very rare,⁵⁹ despite high HTLV-1 prevalence, suggesting that genetic and environmental factors may be involved in its development.^{279,312} In 1996, infective dermatitis began to be referred to as infective dermatitis associated with HTLV-1 (IDH),^{274,277} and criteria for its diagnosis were established in 1998.^{275,276} In 2010, revised criteria for the diagnosis of IDH were suggested,⁵⁶ and these are detailed in Box 192A.3. Given that the diagnosis of HTLV-1 is mandatory to the diagnosis of IDH, it is advised that in endemic areas serology for HTLV-1 be performed in all cases of severe eczema in children and adolescents.⁵⁶

A recently reported study of 42 IDH cases from Bahia, Brazil details the epidemiologic and dermatologic characteristics of the condition.¹²² In this series, approximately two-thirds of the patients are females, and all are of African descent and from underprivileged backgrounds. Of the 42 patients, 41 were perinatally infected with HTLV-1; one with an HTLV-1-seronegative mother had received a blood transfusion early in life. Mean age at onset of IDH was 2.6 years (range, 2 months to 11 years), and in 37% of children skin lesions first appeared before 12 months of life. All patients were symptomatic, with pruritus of mild to moderate intensity. Dermatologically, all patients had lesions on the scalp and retroauricular area; crusting of the nares was found in only 64% of children and in two children was seen only during relapses. Antecubital and popliteal fossae were involved in 57%, and 83% had disseminated IDH (i.e., simultaneous involvement of scalp, neck, trunk, and limbs). Lesions were generally severe and exudative, associated with erythematous scale, and grossly infected. Other lesions noted in fewer patients included erythematous scaly papules, follicular papules (always disseminated), retroauricular fissures, and blepharoconjunctivitis. S.

BOX 192A.3 Major Criteria for Diagnosis of Infective Dermatitis Associated With Human T-Cell Lymphotropic Virus Type 1

1. Lesions of the scalp, ears, retroauricular areas, paranasal and perioral areas, neck, axillae, thorax, abdomen, groin, and other sites. Lesions may be erythematous/scaly, exudative, and/or crusted
2. Crusting of nostrils
3. Chronic, relapsing condition with prompt response to specific appropriate therapy, but recurrence promptly on discontinuation of antibiotics
4. Serologic or molecular evidence of HTLV-1 infection

Fulfillment of criterion 1 requires involvement of three or more areas, including scalp and retroauricular areas. Of the 4 major criteria, 3 are required for diagnosis; 1, 3, and 4 must be present.

aureus was isolated from the skin lesions of 97% of children evaluated bacteriologically; in fewer than 10%, *Streptococcus pyogenes* was detected.

Immunohistologic findings were similar to those from other studies,⁵⁸ in which inflammatory infiltrates in IDH comprise mostly CD8⁺ T cells, as opposed to atopic dermatitis and seborrheic dermatitis, in which CD4⁺ lymphocytes predominate.⁵⁸ The HTLV-1 genome has been detected by PCR in lymphocytes cultured from biopsy specimens of skin lesions in patients with infectious dermatitis, although cultured fibroblasts were negative, suggesting that HTLV-1-infected lymphocytes had infiltrated the skin.²⁷⁷ Cultured keratinocytes from children with infectious dermatitis have been shown to exhibit overexpression of proinflammatory and antiinflammatory cytokines that could be induced directly or indirectly by HTLV-1 infection.³⁵⁷ Secretion of cytokines by HTLV-1-infected cells may amplify or maintain a persistent inflammatory reaction in the skin and, when combined with the enhanced susceptibility to infection induced by HTLV-1-associated immunodysfunction, could result in the clinical manifestations of infective dermatitis. Although likely secreting cytokines that contribute to the disease process, in IDH infiltrating CD8⁺ lymphocytes are typically not activated with cytotoxic granulations, whereas in atopic dermatitis lymphocytes are activated, expressing perforin and granzyme-B and contributing to the inflammatory process.⁵⁸ This distinction, along with the difference in CD4⁺/CD8⁺ ratios among infiltrating cells, may present a distinguishing feature in the differential diagnosis between atopic dermatitis and IDH.^{56,58}

In the Bahia series, all patients responded to antibiotic treatment; trimethoprim-sulfamethoxazole is commonly used. Yet relapse was very common after discontinuation of antibiotics. Although active disease continues in approximately two-thirds of patients, persistent disseminated disease is rare (a single child), indicating long-term improvements over time with treatment. In this series, in which cases have been followed for up to 12 years, the mean age at which IDH disappeared (one-third of patients) was 15 years (range, 10–20 years).

Not infrequently, IDH progresses to HAM/TSP and rarely to ATLL.^{56,122,379} In the Bahia case series, 47% of children with IDH progressed to HAM/TSP in childhood or adolescence, with more than 80% of HAM/TSP cases defined as definite. An association with development of HAM/TSP has been reported from other settings, as well.^{56,379} IDH has similar virologic and immunologic features to HAM/TSP, with high proviral load and high levels of TNF- α and IFN- γ ³⁷⁹; in a Brazilian study, no differences were found between IDH and HAM/TSP patients in the latter two markers. It is suggested, then, that IDH is a risk factor for the development of HAM/TSP.³⁷⁹ IDH may also be a risk factor for progression to ATLL.^{56,59} Progression to ATLL has been seen in the Bahia cohort and others, although much less commonly than progression to HAM/TSP.^{56,122,379} Of 52 cases of ATLL with skin involvement observed in Bahia, 37% of patients reported a history of severe childhood eczema suggestive of IDH,⁵⁵ and flower cells were observed in 17% of a 30-patient IDH cohort in childhood or puberty, possibly representing a prodromal stage of ATLL.

In addition to the risk for subsequent TAM/HSP and ATLL in children with IDH, warranting periodic neurologic examinations as part of follow-up, IDH's other complications, occurring in 30% to 35% of patients, also should be appreciated. *Strongyloides* is a common coinfection in IDH cases. Given its putative role in the pathogenesis of ATLL through stimulating clonal expansion of lymphocytes and its generally asymptomatic nature, *Strongyloides* should be actively sought in all IDH cases and treated when present because appropriate *Strongyloides* treatment can reverse clonal expansion and may reduce the risk for ATLL developing.¹⁶⁷ Other reported complications include crusted (Norwegian) scabies, chronic bronchiectasis, lymphocytic interstitial pneumonitis, and glomerulonephritis, which reflect the systemic complications of HTLV-1 infection. Early death caused by severe bacterial infections with sepsis may occur, and rheumatic heart disease and kidney failure have been reported as causes of death in adolescents with IDH.¹²²

Other Disorders in Adults and Children

Numerous autoimmune disorders have been associated with HTLV-1. In a study of 113 HTLV-1-infected patients in southern Florida, rheumatologic or autoimmune diseases were not uncommon manifestations.²⁰⁹ In two settings, HTLV-1 infection is associated with arthritis.³⁴⁰

in patients with ATLL and in those who are HTLV-1 seropositive but do not have ATLL or HAM/TSP.^{340,382} Polyarthritis is a common presenting feature of ATLL, with some patients manifesting arthritis for as much as 5 years before ATLL diagnosis. Most patients with ATLL-associated arthritis are negative for rheumatoid factor. In patients with HTLV-1-associated arthritis (HAA) without ATLL, onset is typically after 50 years of age, and presentation is a chronic oligoarthritis with large joints (shoulders, knees, and wrists) most commonly affected. As with HAA in ATLL, rheumatoid factor is typically negative. Strong suspicion exists that HAA represents another disease caused by HTLV-1, as opposed to simply HTLV-1 associated, because synovial fluid and tissue in HAA cases contain high proportions of ATLL-like cells, along with HTLV-1 proviral DNA. As well, HAA occurs in HTLV-1 *tax*-transgenic mice,²³⁹ and there are suggestions that HTLV-1 Tax protein may be associated with proliferation of synovial cells, leading to erosion of cartilage and bone.

HTLV-1-associated polymyositis has been well described in patients with HAM/TSP.^{353,354,405,587,590} Muscle biopsy is consistent with myositis with mononuclear interstitial infiltrates, necrosis, and regeneration. HTLV-1 provirus has been identified by *in situ* hybridization in CD4⁺ cells in the inflammatory cell infiltrate.²¹⁷ The mechanism by which HTLV-1 produces disease is unknown. It is probably not a direct viral effect because HTLV-1 does not appear to infect muscle cells.^{353,354} As hypothesized for HAM/TSP, the pathologic process could be the result of an autoimmune response, or it could be caused by the production of cytokines in focal inflammatory infiltrates in muscle by activated HTLV-1-infected CD4⁺ cells and subsequent bystander damage to the myofibers. Cases complicating HAM/TSP may be severe, with diaphragmatic involvement and respiratory failure.²⁹⁹ As well, non-HAM/TSP-associated polymyositis has been noted in HTLV-1-infected carriers without HAM/TSP, with predominance in children.¹⁵⁰ Muscular dystrophy-like presentations have been noted,¹⁵⁰ with onset of muscular weakness in early childhood, initially in the lower limbs and progressing to the upper limbs, in the absence of bladder dysfunction or signs of spinal cord or other CNS dysfunction, markedly elevated muscle enzymes, myopathic pattern on electroneuromyography, and diffuse muscular atrophy on MRI.¹⁵⁰ Polymyositis may be associated with uveitis.²⁶⁵ In some HTLV-1-infected patients coinfecting with HIV, inclusion-body myositis has been noted.¹¹⁰ Therapy includes immunosuppressants and immunomodulators, particularly corticosteroids.^{85,150}

Asymptomatic, subclinical lymphocytic pneumonitis has been described in patients with HAM/TSP, and radiologic studies have shown higher rates of pulmonary involvement in HTLV-1 carriers than in individuals not infected with HTLV-1.³⁹⁴ HTLV-1 carriers have increased risk for pulmonary tuberculosis, cryptococcosis, and community-acquired pneumonia.^{21,269,324} The innate immunosuppression induced by HTLV-1 infection contributes to this and can result in frankly immunosuppression-associated infections such as *P. jirovecii* pneumonia. Pulmonary manifestations vary in HTLV-1-associated lung disease, with bronchiolitis, including diffuse panbronchiolitis, alveolitis, and interstitial pneumonia having been noted.²⁶¹ HTLV-1 proviral load in peripheral blood mononuclear monocytes corresponds to the degree of bronchoalveolar lymphocytosis,³⁵⁵ and HTLV-1 mRNA appears to be upregulated in bronchoalveolar lavage fluid cells, in contrast to peripheral blood mononuclear monocytes.²⁶¹ Bronchoalveolar lavage has shown the presence of a T-lymphocyte alveolitis, with highly soluble IL-2 receptor levels, increased mRNA levels of cytokines and chemokines, and high proportions of HTLV-1-specific CD8⁺ cells also found in lavage fluid from these patients, suggesting that HTLV-1 induces pulmonary inflammation.^{261,497,498,594} On lung biopsy, marked lymphocytic infiltration of the lung is seen.

Destructive lung disease associated with HTLV-1 has been noted in some populations. HTLV-1 has been shown to be a risk factor for the development of bronchiectasis in some endemic areas, especially in the indigenous central Australian population, where HTLV-1 is prevalent (7.2%–13.9%, although rare elsewhere in Australia) and where bronchiectasis exacts a heavy toll in morbidity and mortality¹³⁷; specifically, higher HTLV-1 subtype c proviral loads have been associated with bronchiectasis and higher risk for lower respiratory infections in indigenous Australians.¹³⁶ Annually, 1.5% of indigenous children in

central Australia require admission for bronchiectasis⁹³; in a recent study, 13% of indigenous Australian adults with bronchiectasis died during a single year of follow-up.⁴⁹³

HTLV-1 also has been associated with Sjögren syndrome, a chronic exocrinopathy causing keratoconjunctivitis sicca, xerostomia, and sialadenitis and characterized by a lymphocytic infiltration of the lacrimal and salivary glands; the origin has been hypothesized to be autoimmune. In a study in Japan, HTLV-1 seroprevalence in patients with Sjögren syndrome was 23%, significantly higher than the 3% HTLV-1 seroprevalence in blood donors.⁵²⁰ HTLV-1 antibody titers in HTLV-1-seropositive patients with Sjögren syndrome were significantly higher than those in asymptomatic HTLV-1 carriers and similar to those seen in patients with HAM/TSP. However, in contrast to that in patients with HAM/TSP, the HTLV-1 proviral load in peripheral blood was not consistently high. In a study of HTLV-1-infected patients from Guadeloupe, French West Indies, a sicca-like syndrome was found in almost 80% of patients, approximately half of whom also had neurologic findings.³⁸ HTLV-1 provirus has been identified by PCR in acini cells and inflammatory infiltrates in the labial salivary glands of patients with HAM/TSP, as well as in healthy HTLV-1 carriers with the sicca syndrome.⁵¹⁶ In addition, one of the symptoms of Sjögren syndrome is impaired sweating, and HTLV-1 pX sequences have been identified in samples of eccrine sweat gland epithelia from HTLV-1-infected individuals.⁴⁸⁰ Transgenic animal models have indicated that HTLV-1 is tropic for ductal epithelium of the salivary and lacrimal glands.¹⁹⁷ Human studies also suggest this, and add to the suggestion that HTLV-1 may be causal in some patients with Sjögren syndrome, because expression of *tax* but not other HTLV-1 genes has been reported in the salivary glands of 29% of patients with Sjögren syndrome from areas of Japan endemic for HTLV-1⁵⁰¹ and in 23% of patients with Sjögren syndrome from French regions not endemic for HTLV-1.³²³

As mentioned earlier, the immunosuppression induced by HTLV-1 is associated with a variety of infectious complications in HTLV-1-infected patients, including higher rates of both leprosy cases and leprosy treatment failures in areas of Africa where both conditions are endemic, as well as a generally increased susceptibility to parasitic diseases. Although malaria is common in many HTLV-1-endemic areas, there does not appear to be an association between HTLV-1 and risk for severe malaria. The association between *Strongyloides* and HTLV-1 infection has been discussed previously, including the possible role of *Strongyloides* in the pathogenesis of HTLV-1-related disease.^{79,80,446} As well, HTLV-1 infection is a strong risk factor for the development of *Strongyloides* hyperinfection,^{79,80,223,352} which is often fatal,^{79,80} as well as for refractory *Strongyloides* and the development of gastrointestinal lymphoma in coinfecting patients.⁹⁷

Dual Infection With Human Immunodeficiency Virus Type 1

HIV-1 coinfection in HTLV-1 and HTLV-2 carriers occurs with highest prevalence in large metropolitan areas in Europe, the Americas, and Africa and is probably more frequent than clinicians generally realize because HTLV-1 and HTLV-2 testing is not routine in most HIV programs.⁹⁰ Estimates are that HTLV-1 and HTLV-2 rates in HIV-1-infected persons are 100 to 500 times greater than in the general population.^{39,41} In some endemic settings,^{27,28,149} and in at-risk populations in nonendemic settings, such as intravenous drug users in the United States, 5% to 10% of HIV-1-infected persons may be coinfecting with HTLV-1 or HTLV-2.^{49,68} A recent study in Brazil showed almost 3% of HIV-positive patients also coinfecting with HTLV (64% HTLV-1, 35% HTLV-2).⁷⁰

The natural histories of HIV-1/HTLV-1 and HIV-1/HTLV-2 coinfections appear to be different; HTLV-1 appears to accelerate progression to AIDS⁷⁰ and is a risk factor for developing ATLL and HAM/TSP,⁵³⁸ whereas HTLV-2 may produce an immunologic protection against HIV and delay the progression of immunocompromise.³¹

Indeed during the era before highly active antiretroviral therapy (HAART) (mid-1980s), in a cohort of HIV-1-infected men who have sex with men in Trinidad, progression to AIDS within 48 months of observation occurred in 50% of HTLV-1-coinfecting men, in contrast to less than 10% of men without HTLV-1 coinfection.²⁷ Additional studies in the 1980s also observed accelerated progression to AIDS in

HTLV-1–coinfected individuals.^{207,211,484} HTLV-2 coinfection, in contrast to that with HTLV-1, was rarely implicated with HIV-1 disease progression. Multiple studies in adults with HIV-1/HTLV-1 and HIV-1/HTLV-2 coinfections have been carried out since the advent of HAART in the 1990s,^{30,71,69,218,540} with consistent findings that HIV-1/HTLV-1 coinfection is associated with shortened survival and a possible increase in risk for HAM/TSP and other neurologic conditions,²³⁴ leukemia, and lymphoma,^{39,40,71,83,84} including the otherwise unusual presentation of these conditions in patients with high CD4 counts. On the other hand, HIV-1/HTLV-2 coinfection is associated with delayed progression to both AIDS and death^{39,41} and is associated in some cases with long-term nonprogression of HIV-1.^{170,171} Pediatric data suggest that the findings in HIV-1/HTLV-1–coinfected adults are also seen in children, with HIV-1/HTLV-1–coinfected children more likely to present with HIV disease signs and symptoms, and to die, than HIV-1–monoinfected children, despite higher CD4 cell counts at presentation in the coinfecting cohort.⁴¹⁶ In both adults and children, CD4 levels may be a less reliable predictor of immunodeficiency in HIV-1/HTLV-1–coinfected patients because HTLV-1 may induce elevated CD4 levels through enhancing lymphocyte proliferation, but the function of these cells may be abnormal.^{183,84}

Why the clinical differences between HTLV-1 and HTLV-2 coinfection with HIV-1 exist is of substantial interest, and the answer likely lies with an interaction between the Tax-2 protein and several aspects of the HIV-1 replicative cycle along with the modification of several immunologic phenomena.⁴²⁴

Human T-Cell Lymphotropic Virus Type 2

First reported in 1982 in association with a T-cell variant of hairy cell leukemia,²⁵⁰ HTLV-2 is closely related to HTLV-1,³⁰ with approximately 70% homology in nucleotide sequences²⁷² and sharing a tropism for T lymphocytes^{170,171} and similar mechanisms of transmission.³⁰ Importantly, however, it has not been shown to be a true oncogenic virus like HTLV-1.³⁸¹

HTLV-2 infection is endemic to indigenous central African (pygmies) and Amerindian populations^{203,307} and is epidemic among users of intravenous drugs in urban North and South America, Asia, and Europe.^{307,368} Whereas most HTLV-2 infections in urban North and South America, Asia, and Europe are associated with sharing of HTLV-2–infected needles among intravenous drug users, in central African and indigenous American populations, HTLV-2 is probably an ancient infection that has been maintained in the population by sexual transmission and mother-to-child transmission through breastfeeding.^{197,281,283} As mentioned earlier, HTLV-2's role in disease causation is less clear than that of HTLV-1,¹³¹ but a possible association with lymphoproliferative and neurologic disorders and increased rates of infectious diseases has been suggested.^{52,86,487}

Viral Pathogenesis and Molecular Biology

Characterization at the molecular level of HTLV-2's envelope gene (*env*), LTR genomic region, and *tax* gene have recognized three HTLV-2 subtypes: HTLV-2a, HTLV-2b, and HTLV-2d. A unique HTLV-2 subtype discovered in the Brazilian Amazon region originally was christened HTLV-2c,²³⁵ but subsequent complete sequencing of this strain demonstrated it to be a molecular variant of HTLV-2a.³⁰⁷

Like HTLV-1, HTLV-2 can transform cells in vitro, with experimental evidence suggesting that Tax-2 is able to immortalize CD4⁺ T lymphocytes in vitro by oncogenic activation, as well as by promoting autophagy, resulting in increased survival and proliferation of immortalized T cells.⁴⁴⁸ However, in vivo, HTLV-2 displays a preferential tropism for and induces clonal expansion of cells of the CD8⁺ T-lymphocyte phenotype,¹³¹ whereas HTLV-1 provirus is chiefly found in CD4⁺ T lymphocytes. Whether the difference in cell tropism between HTLV-1 and HTLV-2 may explain the differential pathogenicity between the two viruses is unknown. Differences in the two viruses' *tax* gene expression and Tax protein itself have been explored. *Tax-1* possesses a PDZ binding motif in its sequence, a motif that is crucial for *tax-1*'s cell-transforming activity and absent from *tax-2*.⁹⁶ The results of other gene expressions are also likely involved in the two viruses' divergent virulence. HTLV-1 and HTLV-2 encode accessory proteins p30 and p28, respectively, which possess some homology in amino acid sequence and are required

for in vivo viral persistence.¹³¹ Yet p30 and p28 have distinct host protein interaction profiles, resulting in differential expression of a variety of HTLV-1 and HTLV-2 viral genes.¹³¹

Some molecular differences exist between gene products of the various HTLV-2 subtypes, the clinical importance of which is not clear. Of note, Tax-2 protein appears to differ in length between the HTLV-2a and HTLV-2b subtypes, with the HTLV-2b Tax protein being 25 amino acids longer than the HTLV-2a Tax protein.⁴¹² Functionally, the HTLV-2a Tax protein is a weaker inactivator of the *p53* tumor suppressor gene and a less potent transactivator of the viral LTR in vitro than is the Tax protein from HTLV-1 or HTLV-2b, and limited data suggest that the proviral load may be lower in HTLV-2a–infected than HTLV-2b–infected individuals.^{138,312} To date, nonetheless, no indications suggest that disease associations differ in magnitude or effect between HTLV-2 subtypes.

Epidemiology

It is likely that HTLV-2's ancient origins were, like those of HTLV-1, in central Africa, where STLV-2 has been isolated alongside HTLV-2.⁴⁶⁰ HTLV-2–infected migrants likely brought the virus to the Americas 15,000 to 35,000 years ago across the land bridge once connecting Asia and North America.^{51,280} In the past several decades, HTLV-2 has passed from indigenous Americans to intravenous drug users by sharing of contaminated needles,⁵⁵⁵ resulting in an urban HTLV-2 epidemic among this group in Europe, Asia, and the Americas that is well documented.^{30,86,307,460}

HTLV-2 prevalence is highest among indigenous communities in the Americas, particularly in the Amazon region, where prevalence as high as 58% has been reported in some tribal groups. Rates of 8% to 10% have been noted among the Guaymí of Panama and Costa Rica,⁵⁶⁰; in North American indigenous groups, fewer than 1% of Mayans in the Yucatan are HTLV-2 infected,¹⁸⁸ with higher rates in Pueblo, New Mexico (2–3%),²²⁷ Seminole, Florida (13.2%),³⁰² and Nuu-chah-nulth Amerindians in British Columbia (1.6%).⁴²² HTLV-2 seroprevalence is much higher in Amerindian blood donors in New Mexico than non-Hispanic white donors (1–1.6% vs. 0.009–0.06%, respectively).²²⁷ HTLV-2 prevalence in nonindigenous, non–intravenous drug user populations in South America is low, with 0.1% HTLV-2 prevalence noted in an urban Brazilian cohort of pregnant women²⁰⁰ and less than 0.1% in Brazilian and Venezuelan blood donors.^{104,286}

Although HTLV-2 is endemic in Africa, HTLV-2 seroprevalence appears to be relatively low, although in some settings, such as Malawi, HTLV-2 prevalence exceeds that of HTLV-1.¹⁵⁶ Cases are reported sporadically in West and Central Africa,^{182,539} and serosurveys suggest low prevalence.^{66,148} Only 1 in 907 Gabonese pregnant women screened for HTLV-1 and HTLV-2 was HTLV-2 positive, and HTLV-1 prevalence in the same cohort was 2.1%.¹⁴⁸ HTLV-2 prevalence of 0.8% has been noted in Ivory Coast, 0.05% in Guinea, and 0.02% in Senegal.⁶⁶ In higher risk groups in Africa, however, HTLV-2 prevalence may be higher; 2.1% of female sex workers in Eritrea were noted to be HTLV-2 seropositive.⁹

In the United States, Brazil, Europe, and Southeast Asia, HTLV-2 infection is epidemic among intravenous drug users. Globally, the highest rates among intravenous drug users are seen in southern Vietnam, where more than 60% are HTLV-2 infected,¹⁶³ with HTLV-2 most likely introduced during the Vietnam War by US military personnel.⁴⁶⁰ High rates are also noted in intravenous drug users in south and southeast Brazil^{307,356}; in the United States, rates as high as 20% have been noted in some urban populations.⁴⁶⁰ In the United States, HTLV-2 accounts for most of the HTLV infections in intravenous drug users.⁹⁰ In a study of HTLV-2 and HIV seroprevalence in drug users from eight metropolitan areas in the United States, the overall prevalence of HTLV-2 alone was 15.1%, the prevalence of HIV-1 alone was 9.9%, and that of dual HIV-1/HTLV-2 infection was 3.3%. HTLV-2 prevalence was higher in the Southwest and Midwest than the Northeast, whereas HIV-1 prevalence was highest in the Northeast.²⁸ Rates of HTLV-2 infection in European intravenous drug users are also high, from 1.6% to 8% in Italy,¹⁸⁴ 0.4 to 11.5% in Spain,^{119,459} and 15% in an Irish cohort.¹³⁵

In a recent study of blood donors in North America, 14.7 cases per 100,000 individuals were noted.⁹⁴ Peak HTLV-2 prevalence has been previously noted among middle-aged donors, suggesting an age-cohort

effect linked to an epidemic of intravenous drug use (including sex with an intravenous drug user) in the 1960s and 1970s.⁴⁶⁰ Much lower HTLV-2 rates have been seen in Danish, Swiss, and French blood donors.^{63,129,423}

The geographic distribution of HTLV-2 subtypes varies.^{201,460} HTLV-2a is the predominant infection in intravenous drug users in North America, the British Isles, northern Europe, and southeast Asia,^{135,460} while also being seen in Brazilian Amerindians and intravenous drug users.^{6,307} HTLV-2b is endemic in Central and South American indigenous groups, as well as more common among intravenous drug users in southern Europe.^{6,135,307,460} It is also the most common strain detected in Central and West Africa,⁴⁶⁰ although HTLV-2d is also found in Central African pygmy populations.⁴⁶⁰

Modes of Transmission

HTLV-2, like HTLV-1, is transmitted by transfusion of contaminated cellular blood products, sharing of contaminated needles during injection drug use, from mother to child, and sexually; indeed, parenteral routes of transmission appear to be particularly effective for HTLV-2.³⁸¹

Sexual transmission is also an important mode of HTLV-2 acquisition. Although data are more limited for HTLV-2 than for HTLV-1, sexual transmission of HTLV-2 appears to be an important infection route in multiple populations,⁴⁶⁰ including prostitutes and patients attending STI clinics,^{44,460} where two-thirds of HTLV infections diagnosed are HTLV-2.²⁶⁴ This is especially the case for individuals with both an injection drug use history and a history of STIs.^{68,476,562} High HTLV-2 prevalence is also noted in non-intravenous drug using patients who have STIs.⁴⁷⁴ In Amerindian populations in whom HTLV-2 is common, and injection drug use rare,^{460,560} HTLV-2 prevalence is high among both men and women, and there is a strong association of HTLV-2 infection between spouses.^{313,560} Seropositivity in Guaymi women is associated with an early age at first sexual intercourse, the number of lifetime sexual partners, and the number of long-term sexual relationships; in men, sexual intercourse with prostitutes is associated with seropositivity.³¹³ Preferential male-to-female transmission has been suggested by cross-sectional data, as with HTLV-1; the female preponderance of HTLV-2 infection may indicate more efficient sexual transmission of HTLV-2 from men to women than vice versa, and higher HTLV-2 proviral loads in seropositive males are associated with higher rates of HTLV-2 transmission to their partners.³⁷² Prospective incidence data are sparse; the US study referenced earlier showed equivalent proportions of female-to-male and male-to-female transmissions.⁴⁶² In HTLV-2-positive blood donors, a history of sexual contact with an intravenous drug user or an HTLV-2-infected sexual partner was associated with increased risk for HTLV-2 seropositivity.⁴⁷⁵

Injecting drug use is the primary mode of HTLV-2 acquisition in North America, Europe, Asia, and parts of Brazil, where HTLV-2 is endemic among injection drug users.^{86,460} In a study of HTLV-infected blood donors (the Retrovirus Epidemiology Donor Study), HTLV-2 infection was associated significantly with injection drug use or sexual contact with an injection drug user, whereas HTLV-1 infection was not.⁴⁷⁵ Other risk factors, such as seven or more sexual partners, were common to both HTLV-1 and HTLV-2. Sex with an injection drug user was a particular risk factor for women; 65% of HTLV-2-infected women reported that they had a sexual partner who used injection drugs, and 20% of women reported that they also injected drugs themselves. HTLV-2 infection in drug users has been associated with nonwhite race, older age, markers of previous hepatitis B virus infection, the use of a specific needle-sharing practice called backloading, a history of herpes simplex virus type 2 infection, and a history of receiving money for sex.^{76,477,561} In a Spanish study of young injection and noninjection heroin users, approximately 3% of the cohort was HTLV infected, with all HTLV infections being HTLV-2.¹¹⁹ Indeed, almost all cases of HTLV-2 reported from Spain have been in injection drug users, and the prevalence in Spain in this group is one of the highest in Europe.^{43,305,524} Among injection drug users in Spanish prisons, HTLV-2 prevalence is 18%, whereas outside prisons, HTLV-2 rates countrywide in Spain average 5%.^{83,84} In an Italian study, seroprevalence among injection drug users for HTLV-2 was 8.2% versus 2.1% for HTLV-1.

HTLV-2 also has been detected in the breast milk of carrier mothers,⁴⁶⁰ and mother-to-child transmission has been described in those who

breastfeed.^{215,274,275,277,278,546} High proviral load in the mother is a clear transmission risk factor.⁴⁶¹ Prolonged breastfeeding is common in Amerindian populations, and high prevalence rates (12–16%) have been documented in children younger than 15 years in several Central and South American indigenous populations.^{61,151,560} Like HTLV-1, HTLV-2 appears to be transmitted infrequently in the absence of breastfeeding.^{170,171,202,255} and breastfeeding interruption has been shown to prevent perinatal transmission of HTLV-2.⁴⁴⁹ Passive immunization with HTLV-2 hyperimmunoglobulin in rabbits prevented blood-borne transmission of HTLV-2-infected cells.³⁵⁷ Only HTLV-2, and not HTLV-1, immunoglobulin was effective in preventing HTLV-2 transmission, a finding suggesting that despite some cross-reactivity on conventional ELISAs, cross-neutralization between the viruses is minimal or nonexistent.³⁵⁷

Clinical Disease

As mentioned previously, HTLV-2 is less virulent than HTLV-1, its main associations being lymphocytosis, infections, and inflammatory manifestations.²⁹ Why this is is unclear. It has been suggested the reasons lie in higher expression of gene products inducing viral latency (p28 and tRex) as well as differences between Tax-1 and Tax-2 between the two viruses.⁹⁹

Whereas HTLV-1 has been causally linked to diseases such as ATLL and HAM/TSP, as detailed earlier, to date HTLV-2 has not, although an association exists between HTLV-2 and HAM/TSP, especially in HIV-coinfected individuals.⁴³⁴ In otherwise healthy individuals, HTLV-2 has been associated with increased mortality from a variety of causes.^{54,400} In a prospective cohort study of non-HIV-infected American blood donors, controlling for intravenous drug use, all-causes mortality was increased among HTLV-2-infected patients, although no single cause of death could be identified as responsible for the effect.⁴⁰⁰ Another prospective study noted a similar effect of HTLV-2 on all-causes mortality, tying the effect to an increase in cancer mortality.⁵⁴ Specific cancers noted in excess included lung, cervical, and colorectal cancer, as well as hepatocellular carcinoma, leukemia, lymphoma, and melanoma,⁵⁴ suggesting that HTLV-2 may have a facilitating role in cancer development similar to that in HIV, mediated by reduced immunosurveillance of malignant cells in emerging neoplasms.⁵⁴

Although HTLV-2-infected patients commonly have hematologic abnormalities, and cases have been reported of hairy cell leukemia, large granulocytic leukemia, T-prolymphocytic leukemia, and cutaneous lymphoma, including mycosis fungoides, in larger studies HTLV-2 has not been proved to cause leukemia/lymphoma, as has HTLV-1.^{280,460} Importantly, HTLV-2 integration in transformed cell or tumor samples has not been detected.^{155,310} Yet, although HTLV-2 has not demonstrated a causal role in leukemia/lymphoma, HIV-coinfected individuals may be at higher risk for T-cell leukemia/lymphoma, suggesting that the expansion of HTLV-2-transformed lymphocytes may be prone to dysregulation in the presence of HIV-induced immune system dysfunction and highlighting the oncologic risks for HTLV-2/HIV-coinfected patients.⁴⁶⁰

Evidence suggests that HTLV-2 may be associated with neurologic disorders ranging from a spastic paraparesis-myelopathy similar to HAM/TSP to more widespread involvement of the CNS.^{365,434} Myeloneuropathies indistinguishable from HAM/TSP have been reported in patients infected with HTLV-2 alone or coinfecting with HIV-1.^{45,226,365,370} In a prospective Brazilian cohort, 10% of HTLV-2/HIV-coinfected patients developed HAM/TSP over a 7-year observational period, whereas no patients infected with only HTLV-2 did, suggesting HIV coinfection is a substantial risk factor for developing neurologic disease when infected with HTLV-2.⁴³⁴ In addition, sensory neuropathies have been noted in patients with HTLV-2 alone,⁵³ as well as with HIV coinfection,⁵⁹⁸ and a chronic neurodegenerative disorder with ataxia as a prominent feature has been reported in HTLV-2-infected individuals.^{208,483}

An increased risk for other infections in HTLV-2-infected patients has been suggested, including serious infections such as pneumonia and pyelonephritis.⁴⁶⁰ An initial report from San Francisco described an association of HTLV-2 seropositivity and bacterial infections, particularly skin and soft tissue infections and bacterial pneumonia, but the results were confounded by intravenous drug use, which in itself

could increase the risk for infections, in nearly all HTLV-2–seropositive patients.³⁵⁰ In a case-control study of intravenous drug users from Baltimore with an overall HTLV-2 seroprevalence of 7%, no significant association between HTLV-2 seropositivity and the development of bacterial pneumonia, infective endocarditis, and skin abscess was found.⁴⁶⁰ However, a prospective study of HIV-negative, HTLV-1–infected and HTLV-2–infected, and uninfected individuals from several large American cities found that HTLV-2–infected persons were more likely to develop asthma, acute bronchitis, bladder or kidney infection, arthritis, and pneumonia than HTLV-2–uninfected persons and that HTLV-1 infection was associated with only bladder or kidney infection or arthritis.³⁶⁹ Although suggesting that HTLV-2 may inhibit immunologic responses to bacterial infections,³⁶⁹ the natural history and clinical manifestations of HTLV-2 need further delineation in the context of ongoing prospective studies.

Given HTLV-2's unclear pathogenic role, treatment of HTLV-2 is not established and has not been evaluated systematically.³⁸¹

Other Forms of Human T-Cell Lymphotropic Virus

Three new primate T-cell lymphotropic viruses have been discovered in recent decades. In East Africa in 1994, STLV-3 was described in a nonhuman primate.¹⁹³ In the mid-2000s, the identification of HTLV-3 and HTLV-4 among bushmeat hunters in Cameroon demonstrated greater HTLV diversity than was recognized previously. Preliminary data suggest that HTLV-3 comes from a simian origin, whereas HTLV-4 does not appear to have a known simian counterpart, despite extensive screening of monkeys in Cameroon.³¹⁰ It is predicted that HTLV-3 and HTLV-4 may be widespread in central Africa, although of low prevalence.^{74,580}

Both of these newer forms of HTLV cross-react with current HTLV-1 and HTLV-2 assays, giving positive or indeterminate results and highlighting the need for more specific subtype testing. Currently PCR assays specific for PTLV-3 and PTLV-4 are required for HTLV-3 or HTLV-4 detection.⁴²¹ Although both HTLV-3 and HTLV-4 contain sequences encoding for some of the proteins believed to be involved in the pathogenesis of HTLV-associated T-cell malignancies,⁴²¹ no clinical maladies in either humans or simians have been attributed to HTLV-3 or HTLV-4 to date,^{134,310,421,504} and concern exists about the spread of infection by blood donations from infected persons or by those who participate in primate hunting. A 2010 sample from New York State of more than 1000 HTLV-infected patients, HTLV-indeterminate blood donors, and other subjects with epidemiologic or clinical features suggesting risk for HTLV-associated disease was negative for HTLV-3 and HTLV-4.⁴²¹ Molecular studies have established that in terms of transcriptional activation, Tax-3 is a functional analogue of Tax-1 and is distinctly different from Tax-2, suggesting that HTLV-3 may have

pathogenic features in common with HTLV-1.⁹⁶ HTLV-4's Tax protein has similarities to that of HTLV-2, missing the PDZ motif present in Tax-1 and Tax-3 important for cellular signal transduction and trans-formation, as is Tax-2.⁵⁰⁴ Further study is required to understand more clearly what implications these newer forms of HTLV have on human disease.

Future Directions

Effective treatments for HTLV-1-associated disease are of great clinical interest, and trials are ongoing in pursuit of HTLV-1 therapies (Table 192A.4).

LENTIVIRUSES: HUMAN IMMUNODEFICIENCY VIRUS TYPE 2

First identified in 1986, HIV-2 has a morphology and life cycle similar to those of HIV-1 but with significant antigenic, biologic, epidemiologic, and clinical differences (Table 192A.5). The viruses have similar modes of transmission, and each can result in immune depletion and AIDS. However, whereas HIV-1 has a global distribution, HIV-2 is confined primarily to West Africa and is found only sporadically in Europe, the United States, and other countries. In all settings in recent decades, the incidence and prevalence of HIV-2 have declined and HIV-1 infection has become more likely. The clinical course of HIV-2 infection is generally more indolent than that of HIV-1; the clinical latency period is longer, progression to AIDS is less common, and rates of perinatal and sexual transmission are lower. The basis of such differences in natural history between these two lentiviruses is unknown and may result from characteristics of the virus, the host, or both.

Viral Genome and Pathogenesis

Like HIV-1, HIV-2 is thought to have entered human populations through cross-species transmission. HIV-2 is closely related to simian immunodeficiency virus from the sooty mangabey (SIV_{SM}) indigenous to West Africa. Nine genetic groups of HIV-2 have been identified. However, current data suggest that only HIV-2 groups A and B are established in significant amounts in the human population,⁴⁷ with the remaining groups being identified in single individuals. Intergroup recombinant forms of HIV-2 involving groups A and B have been identified.^{231,587,588} No significant differences in transmission, pathogenicity, or disease progression have been observed between the HIV-2 groups A and B.

The genomes of HIV-1 and HIV-2 encode 16 viral proteins that play roles essential for HIV infection and replication. Three major genes, *gag*, *pol*, and *env*, encode structural proteins (capsid, matrix, nucleocapsid, and p6), viral enzymes (protease, reverse transcriptase, and integrase),

TABLE 192A.4 Registered Studies in Human T-Cell Lymphotropic Virus (2010–15)

Clinical Trial Identifier	Sponsor (Location)	Initiation Date	Objectives
NCT01867320	NINDS (USA)	May 2013	To evaluate the effect of raltegravir in decreasing viral load of patients with HAM/TSP
NCT01754311	Centre Hospitalier Universitaire de Fort-de-France (France)	December 2012	To evaluate prevalence and influence of CT/TT genotype in HTLV-1 infection and HAM/TSP
NCT01712659	NCI (USA)	October 2012	To test safety and efficacy of ruxolitinib in treating HTLV-1–associated ATLL
NCT01472263	Hospital Universitario Professor Edgard Santos (Brazil)	November 2011	To evaluate the efficacy of pentoxifyline in HTLV-1 patients with neurologic diseases: HAM/TSP or neurogenic bladder
NCT01640002	Hospital Universitario Professor Edgard Santos (Brazil)	July 2011	To assess the efficacy of propantheline bromide to treat OAB in HTLV-1–infected patients
NCT01343355	St. Marianna University School of Medicine (Japan)	April 2011	To evaluate the efficacy of tamibarotene in motor and urination function, HTLV-1 proviral load, immunologic parameters, and markers in the spinal fluid in patients with HAM/TSP
NCT01274533	Columbia University (USA)	January 2011	To determine the efficacy of lenalidomide monotherapy in relapsed or refractory HTLV-1–associated ATLL

ATLL, Adult T-cell leukemia/lymphoma; HAM/TSP, HTLV-1–associated myelopathy/tropical spastic paraparesis; HTLV-1, human T-cell lymphotropic virus type 1; OAB, overactive bladder. From Nicolas D, Ambrosioni J, Paredes R, et al. *Expert Rev Anti Infect Ther*. 2015;13(8):947-963.

TABLE 192A.5 Comparison of Human Immunodeficiency Virus Types 1 and 2

Characteristic	HIV-2	HIV-1
Viral genome	Genes encoding structural proteins: <i>gag, pol, env</i> Genes encoding regulatory proteins: <i>tat, rev</i> Genes encoding accessory proteins: <i>vif, vpr, vpx</i>	Genes encoding structural proteins: <i>gag, pol, env</i> Genes encoding regulatory proteins: <i>tat, rev</i> Genes encoding accessory proteins: <i>vif, vpr, vpu</i>
Co-receptor usage	CCR5, CXCR4, CCR3, CCR8, GPR1, GPR15, CXCR6, RDC1 and apj ³⁵⁹	CCR5, CXCR4
Geographic distribution	West Africa: Guinea-Bissau, Burkina Faso, the Gambia, Senegal, Ivory Coast Outside of West Africa, primarily in countries with political and economic ties with West Africa: Portugal, France, Germany, Brazil	Global
Prevalence over time	Declining ^{109,352}	Increasing
Mode of transmission	Sexual, blood-borne, mother to child	Sexual, blood-borne, mother to child
Risk of mother-to-child transmission (without antiretroviral prophylaxis)	1.2–4% ^{4,391}	24.4–24.7%
Viral set point	2500 copies/mL (28-fold lower than HIV-1) ⁸	70,000 copies/mL
Progression to AIDS (without antiretroviral treatment)	Infrequent (probability of remaining AIDS free at 1 and 3 years being 96.6% and 94.5%, respectively) ³³³	Frequent
Increase in mortality above that of HIV-seronegative individuals	2-fold to 4-fold increase ^{48,436,452}	10-fold increase
Mortality rates	52 deaths/patient-years observed ³³²	87 deaths/patient-years observed
Antiretroviral medication resistance	Intrinsically resistant to nonnucleoside reverse transcriptase inhibitors ⁵⁷⁹ and fusion inhibitors ^{437,578}	

AIDS, acquired immunodeficiency virus; HIV, human immunodeficiency virus; LTR, long terminal repeat.

and envelope proteins (GP120 and GP41). The remaining genes code for regulatory proteins (Tat and Rev) and accessory proteins (Vif, Vpu/Vpx, Vpr and Nef). Vpu is found exclusively in HIV-1, and Vpx is found in HIV-2. The function of and the interactions between the various HIV proteins in the viral lifecycle,²⁹⁶ as well as how HIV accessory proteins interact with host cellular proteins to overcome host pathways and processes that act to limit viral infection and replication, are areas of active investigation.^{496,334}

Both HIV-1 and HIV-2 bind to CD4 receptors on the surface of susceptible cells. In addition to CD4, binding to a chemokine coreceptor is required for effective infection of target cells. Chemokines act as potent chemoattractants of a large variety of mononuclear cells to sites of inflammation or secondary lymphoid organs by interacting with chemokine receptors. The seven-transmembrane G-protein-coupled chemokine receptors CCR5 and CXCR4 are the major coreceptors used for HIV-1 and HIV-2 infection in vivo. Binding of HIV to chemokine receptors together with CD4 molecules permits fusion of the virus and cell membranes to occur and ultimately viral entry into target cells. Cell tropism of HIV is determined by the expression of CD4⁺ and these coreceptors.

The CCR5 receptor is used by the majority of HIV-1 isolates (R5 viruses), but some isolates from individuals with more advanced immunodeficiency use CXCR4 (X4 viruses) instead of or in addition to CCR5. CXCR4-binding viruses emerge late in disease in as many as 50% of patients with AIDS. The presence of X4 virus, as well as a switch from CCR5 to CXCR4 use, is associated with accelerated rate of disease progression, although it is not a prerequisite because not all infected individuals demonstrate this coreceptor switch.

Whereas both HIV-1 and HIV-2 infect CD4⁺ T lymphocytes and use CXCR4 or CCR5 coreceptors for cell entry, primary HIV-2 isolates can use multiple additional coreceptors to infect indicator cell lines in vitro,³⁵⁹ including CCR3, CCR8, GPR1, GPR15, CXCR6, RDC1, and apj.

The cytopathicity of HIV-2 appears similar to that of HIV-1 and is determined in part by the type of coreceptor used for cell entry. In an in vitro study comparing HIV-1 and HIV-2 coreceptor use and cytopathicity in human lymphoid cells, HIV-2 specificity for the CCR5 coreceptor alone or in combination with other coreceptors was associated with restricted cytopathicity, whereas specificity for CXCR4 was linked to a more virulent phenotype, as observed for HIV-1.⁴⁷⁴ Coreceptor use

of primary HIV variants isolated from individuals who had undetectable viral loads, preserved CD4⁺ cell counts, and a nonprogressive clinical course was compared with those from individuals with more progressive disease. In this comparison, HIV-2 variants were found to use CCR5, GPR15, and CXCR6 with high efficiency regardless of the clinical course, but only HIV-2 variants isolated from individuals with viremia or overt progressive disease could use CXCR4. X4 variants were not observed in all individuals with progressive infection, a finding indicating that the capacity to use CXCR4 is not the only determinant of HIV-2 virulence. Studies have shown that the use of CCR1, CCR2b, and CCR3 coreceptors is rare.⁶⁰ Thus the lesser virulence of HIV-2, in contrast to that of HIV-1, does not appear to be the result of a restriction in coreceptor use or lower intrinsic cytopathic potential. In addition, the broadening of the coreceptor use did not necessarily increase the pathogenic potential of HIV-2 strains.⁵⁴⁸

Lentiviral envelope glycoproteins can induce production of cytokines and other immunologic disturbances; differences in the effect of the HIV-1 and HIV-2 envelope glycoprotein also could contribute to differences in the pathogenicity of the viruses. Recombinant HIV-2 envelope glycoprotein is superior to the HIV-1 envelope in stimulating the production of IFN- γ and IL-16, both of which inhibit viral replication, and less effective in producing expression of IL-4, which stimulates viral replication.^{380,479} The HIV-2 envelope glycoprotein inhibits T-cell proliferation more than does the glycoprotein of HIV-1 in vitro and also was found to inhibit expression of cell surface activation markers.⁸⁷ The presence of an HIV-2 protein that reduces immune system stimulation may decrease replication, result in lower levels of HIV-2 viremia, and decrease CD4⁺ cell apoptosis. The rate of total lymphocyte apoptosis has been found to be lower in HIV-2 than in HIV-1 infection.³⁴² In one study, 50% of peripheral blood mononuclear cells from HIV-2-infected commercial sex workers resisted in vitro challenge with CCR5-dependent HIV-1, but not CXCR4-dependent HIV-1.²⁷⁰ Additionally, high levels of β -chemokines RANTES (regulated on activation, normal T-cell expressed and secreted), macrophage inflammatory protein (MIP)-1 α , and MIP-1 β , the natural ligands of the CCR5 receptor, were secreted when these resistant peripheral blood mononuclear cells from HIV-2-infected individuals underwent stimulation. These investigators hypothesized that β -chemokine-mediated resistance could play a role in the potential protection of some HIV-2-infected individuals from secondary HIV-1 infection.

Epidemiology

Although the global prevalence of HIV-2 infection has been far exceeded by that of HIV-1, HIV-2 remains endemic in former Portuguese and French colonies in West and South Central Africa, including Guinea-Bissau, Burkina Faso, the Gambia, Cape Verde, Senegal, and the Ivory Coast, as well as in Angola and Mozambique.³²⁵

In these settings, there has been diverging epidemiology between HIV-2 and HIV-1 infections, with the prevalence of HIV-2 declining while that of HIV-1 has increased. Guinea-Bissau, for example, had the highest recorded adult prevalence of 8.9% in 1987.⁴³⁶ In the decade between 1996 and 2006, Guinea-Bissau had a reduction in the prevalence of HIV-2 from 7.4% in 1996 to 4.4% in 2006, particularly among men and women younger than 45 years. Over the same time period, the prevalence of HIV-1 increased from 2.3% to 4.6%.^{109,321} Mathematical models predict a continued decline in HIV-2 acquisition and prevalence, with eventual extinction of HIV-2 in areas of West Africa.¹⁶⁰

Outside of the countries in West and South Central Africa in which it is endemic, HIV-2 has been reported primarily in regions in Europe, South America, and India with historical socioeconomic ties to West Africa. In Europe, the greatest numbers of HIV-2 cases have been reported in Portugal, France, and Germany. The cultural and economic ties of Portugal to its former colonies in West Africa likely facilitated the spread of HIV-2 to Europe and possibly Brazil, also a former Portuguese colony. Portugal has experienced great changes in the epidemiology of HIV-2 infections over time. By the end of 2008, the cumulative number of HIV-2 infections in Portugal was 1813. Until 2000, the majority of HIV-2-infected individuals in Portugal were Portuguese-born males living in the north of the country, many with direct or indirect relationships with Africa. In contrast, from 2000 to 2007, most of the patients diagnosed with HIV-2 infection were females of West African origin living in the capital city of Lisbon.^{79,80} These shifts in infection trends have been attributed to sociopolitical events in West African countries and population migration both to and within Portugal. Indigenous HIV-2 transmission also may occur, inasmuch as HIV-2 infections not directly linked to West Africa have been reported in Portugal, France, and Spain.

Sociopolitical pressures and international migration have resulted in the identification of individuals infected with HIV-2 in other countries as well. In England, Wales, and Northern Ireland, the prevalence of HIV-2 infection among clinic attendees with STIs was 0.006% (6 per 104,006) in 2002. Most of these patients likely were infected through heterosexual intercourse in West Africa. Of 1324 HIV-infected adults, 917 (69%) were HIV-1 infected and 52 (6%) were HIV-2 or HIV-1/HIV-2 coinfecting; the HIV type was not reported in the remaining 355 (27%). The ratio of HIV-2 and HIV-1/HIV-2 dual infections to HIV-1 infections varied greatly by country of infection, with the Gambia (11.7–15.2%) and Ivory Coast (7.2–9.8%) having a high proportion of HIV-2 infections and Nigeria (0.7–1%) a low proportion.¹³² From 1988 to June 2010 in the United States, 166 cases met the CDC working case definition for HIV-2 infection. Most cases (66%) were concentrated in the northeastern United States, particularly New York City, and 81% occurred among individuals born in West Africa.⁵²³ Between 2000 and 2008 in New York City alone, 62 HIV-2-infected individuals were identified, of whom 82.7% (48 per 62) were born in West African countries.⁵²³ It is important to note that in the past, HIV-2 infection has been difficult to diagnose, hampered by diagnostic algorithms that inadequately distinguished HIV-1 and HIV-2 mono-infections and HIV-1/HIV-2 dual infection. Now that better HIV-2 diagnostics are available, it may be found that although HIV-2 infections contribute only marginally to the overall global HIV burden, HIV-2 may be less geographically restricted than previously thought.

Dual Infections With Human Immunodeficiency Virus Types 1 and 2

Dual infection with HIV-1 and HIV-2 has been observed in areas that are endemic for both viruses.^{125,176,417} In a cross-sectional survey of Guinea-Bissau households, the prevalence rates of HIV-1 and HIV-2 are similar (4.6% and 4.4%, respectively), but HIV-1/HIV-2 dual infections remained rare (0.5%).¹²⁴ In the United States, 11% (19 per 166) of HIV-2 cases were confirmed to be HIV-1/HIV-2 coinfections.⁵²³

Although some reports suggested that infection with HIV-2 may be protective against subsequent acquisition of HIV-1 infection, this was not confirmed in other studies.^{16,384,528,529,573} In two studies, HIV-2-positive subjects actually had a tendency toward a higher risk for acquiring HIV-1 infection than did seronegative individuals.^{385,576} Susceptibility to dual HIV-1 and HIV-2 infection was studied in a macaque model of HIV infection.^{404,442} The timing of secondary virus exposure was found to be a critical factor in the risk for acquiring infection. Productive mixed infections were established with simultaneous exposure or when viral challenge occurred within 4 weeks after primary infection developed. However, animals exposed at 8 weeks or more after primary inoculation were resistant to secondary infection. The mechanism of protection is not known.^{404,442}

A retrospective examination of data from the long-term follow-up of a cohort of members of the Guinea-Bissau police force suggests that the progression of HIV-1 infection may be inhibited by concomitant HIV-2 infection, particularly when HIV-2 infection occurred before HIV-1 infection. Differences were found in progression of infection, with the median time to developing AIDS being 68 months for those with HIV-1 infection alone and 104 months for individuals with HIV-1/HIV-2 dual infection. When those with dual infection were stratified by whether HIV-2 infection occurred before or simultaneously with HIV-1, the median times to development of AIDS were 129 months and 88 months, respectively.¹⁴⁷

Mode of Transmission

The modes of acquisition of HIV-2 are identical to those of HIV-1: heterosexual and homosexual intercourse, intravenous drug use, receipt of contaminated blood products, and transmission from mother to child. The infectivity of HIV-2 is lower than that of HIV-1, and transmission of HIV-2 by sexual intercourse and from mother to child is much less frequent than that observed with HIV-1.²⁵²

Sexual Transmission

The likelihood of sexual transmission of HIV depends in part on the quantity of HIV in genital tract secretions, which correlates with plasma viral loads. Accordingly, because plasma viral loads are higher in those with HIV-1 infection compared with HIV-2, HIV-1 is detected in semen more commonly and at higher quantities. In one report, HIV-2-infected subjects had a 0.7 log₁₀ lower HIV semen viral load than those with HIV-1, even after adjusting for plasma viral load.¹⁹⁰

Female genital shedding of HIV is important in both heterosexual and mother-to-child transmission of the virus. In a cross-sectional sampling of HIV-infected women living in Dakar, Senegal, HIV-1 shedding occurred more commonly than did shedding of HIV-2. HIV-2 shedding was associated with older age, severe vitamin A deficiency, advanced HIV disease, and CD4⁺ cell counts lower than 200 cells/mm³. Viral shedding was not detected in any women with HIV-1/HIV-2 dual infection.⁴⁷⁷ In a subsequent study of HIV-infected women in Senegal, again HIV-1-infected women were more likely to shed virus and to have high levels of virus in the genital tract than those infected with HIV-2: 78% versus 58%, respectively. Viral shedding correlated more with plasma viral load than HIV type or CD4 count. HIV-1 and HIV-2 shedding was always detected in women with genital or cervical ulcerative disease. Women with HIV-1/HIV-2 dual infections were not included in this study.²¹²

Perinatal Transmission

Perinatal transmission of HIV-2 appears to be a rare occurrence, with vertical transmission from breastfeeding mothers with HIV-2 infection in the absence of ART being less than 4%.^{4,390,408} In a large prospective study from the Ivory Coast, the risk for perinatal transmission from HIV-1-infected mothers was 21-fold greater than from HIV-2-infected mothers; transmission rates were 24.7% from HIV-1-infected mothers versus 1.2% from HIV-2-infected mothers.⁴ In another large study in the Gambia, the estimated rate of mother-to-child transmission of HIV-2 was 4% compared with 24.4% for HIV-1. In this study, three of seven HIV-2-infected infants were infected after reaching 2 months of age, a finding suggesting that HIV-2, like HIV-1, can be transmitted postnatally through breast milk.³⁹¹

In a large French cohort of 8660 HIV-infected mothers who delivered babies between 1994 and 2007, 2.6% of the women were HIV-2 monoinfected. The mother-to-child transmission rate was much lower for HIV-2-infected women than for those infected with HIV-1 (0.6% vs. 5.2%) and was most pronounced in those women not receiving ART and those receiving nucleoside reverse transcriptase inhibitor (NRTI) monotherapy. The mother-to-child transmission among women with CD4 cell counts greater than 350 cells/mm³ was significantly lower in HIV-2-infected mothers than in HIV-1-infected mothers. For those women with severe immunosuppression (CD4 cell counts <200 cells/mm³), however, the risks for transmission were more similar between the groups, 5.3% and 9%, respectively, for women infected with HIV-2 and HIV-1.⁷³ Maternal plasma viral load at delivery has been demonstrated to be a significant risk factor for perinatal transmission of both HIV-1 and HIV-2 infection. Among mothers in the Gambia, for every 1 log₁₀ increase in plasma RNA, the odds of transmission were 2.7 for HIV-1 and 2.8 for HIV-2.³⁹¹ After adjusting for viral load, the odds for transmitting HIV-1 were similar to those for HIV-2; this finding suggests that the level of viremia, as opposed to the type of virus, is the major determinant of the difference in mother-to-child transmission rates between HIV-1 and HIV-2.

HIV transmission from women who are dually seropositive for HIV-1 and HIV-2 has been described; HIV-1 appears to be transmitted more efficiently than does HIV-2, and HIV-1 transmission rates from dually infected women are similar to those from women infected with HIV-1 alone. Transmission of dual infection to the infant, although a rare occurrence, has been described. In the Ivory Coast cohort, 19% of women with HIV-1/HIV-2 dual infection transmitted HIV to their infants; of 11 infected infants, 10 were infected with HIV-1 alone and 1 was dually infected.⁴

Diagnosis of Human Immunodeficiency Virus Type 2

The CDC and the US Preventive Services Task Force both recommend routine HIV screening for adolescent and adult patients unless the patient declines testing. This “opt-out” testing is offered regardless of whether the patient or the health care provider identifies a specific risk for acquisition of HIV infection. If risk factors are identified that place the patient at increased risk for HIV acquisition, annual or more frequent testing may be recommended.^{67,363}

The current HIV testing algorithm (Fig. 192A.5) better detects HIV-2 mono-infection and HIV-1/HIV-2 dual infections. Testing begins with a US Food and Drug Administration (FDA)-approved antigen/antibody combination immunoassay that detects HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen to screen for established infections with HIV-1 or HIV-2 and for acute HIV-1 infection. Because of the use of the antigen/antibody screening immunoassay, this algorithm identifies HIV infection sooner after infection than previous immunoassays. For specimens that are nonreactive on this initial immunoassay, no further testing is required. Specimens reactive to the antigen/antibody combination immunoassay are then tested with an antibody assay that differentiates between HIV-1 antibodies and HIV-2 antibodies. The use of the HIV-1, HIV-2 antibody discriminating assay allows the more accurate diagnosis of HIV-2 mono-infection and HIV-1/HIV-2 dual infection. If the differentiation test is reactive, the result is positive for HIV-1, HIV-2, or both. Specimens reactive by antigen/antibody combination immunoassay but negative or indeterminate for antibody by the type-differentiating immunoassay would proceed to HIV-1 nucleic acid testing for resolution of HIV-1 infection status. Individuals with a positive HIV-1 nucleic acid test and a negative or indeterminate result on the HIV-1, HIV-2 differentiation test are considered to have acute HIV-1 infection. Specimens reactive for HIV-2 with or without reactivity to HIV-1 should be confirmed with a supplemental HIV-2 antibody test such as a HIV-2 Western blot. Ideally, to confirm HIV-2 infection, HIV-2 virus would be isolated by nucleic acid testing, particularly demonstrating HIV-2 proviral DNA in peripheral blood monocytes because HIV-2 viral loads may be low. Currently, there are no FDA-approved qualitative or quantitative HIV-2 nucleic acid assays, and such testing is available through the CDC.⁸⁹

Natural History

Although HIV-2 is fully pathogenic in humans and may lead to AIDS that is indistinguishable from HIV-1-associated AIDS,^{332,333} the clinical course of HIV-2 infection has been found to be more indolent, characterized by a longer asymptomatic phase with slower CD4 cell depletion and progression to AIDS than that of HIV-1 infection.^{306,326,327,430} HIV-2 infection may resemble a slowly progressive or nonprogressive HIV-1 infection, with 86% to 95% of people infected with HIV-2 being long-term nonprogressors.⁵⁴⁹ Compared with that of HIV uninfected

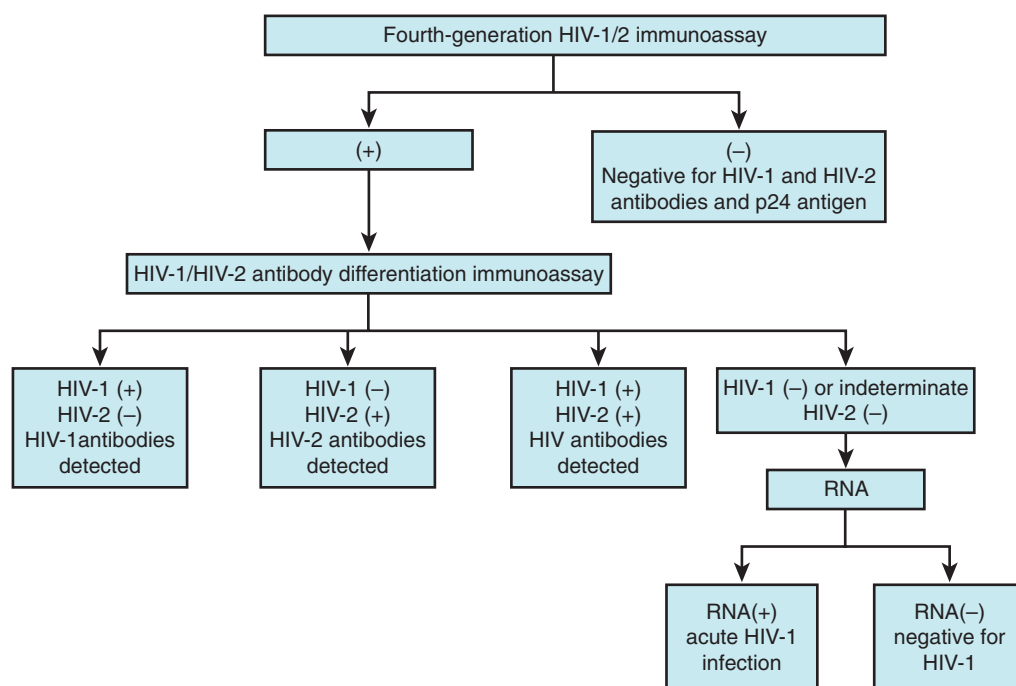

FIG. 192A.5 Recommended laboratory HIV testing algorithm for serum or plasma specimens. (From Centers for Disease Control and Prevention and Association of Public Health Laboratories. Laboratory testing for the diagnosis of HIV infection: updated recommendations. 2014. <https://stacks.cdc.gov/view/cdc/23447>.)

individuals, the HIV-2 mortality rate is increased by 2-fold to 4-fold, in contrast to a 10-fold increase with HIV-1 infection.^{48,436,452}

Similar to those with HIV-1 infection, the clinical course for those infected with HIV-2 can be heterogeneous. But whereas most HIV-1-infected individuals experience disease progression to AIDS, most HIV-2-infected individuals experience little or no disease progression, with only a minority progressing to AIDS. For asymptomatic HIV-infected individuals, CD4 cell counts are higher in those infected with HIV-2 than in those infected with HIV-1 (946 cells/ μ L and 560 cells/ μ L, respectively).³⁰⁶ Among individuals enrolled in the French HIV-2 cohort, immunosuppression as indicated by CD4 cell depletion was correlated with clinical progression of disease, with CD4 cell counts of 482 cells/ μ L, 293 cells/ μ L, and 81 cells/ μ L for individuals at CDC stages A, B, and C respectively.³³³ In this cohort, disease progression occurred infrequently, with the probability of remaining AIDS-free at 1 and 3 years being 96.6% and 94.5%, respectively. Only 19 of the 152 (12.7%) patients classified as CDC group A or B at enrollment experienced at least one group B or C event. Only 9 of those who progressed developed AIDS. The most common AIDS-defining events were tuberculosis and wasting syndrome. Overall survival rates within the cohort were 97% and 93.4% at 1 and 3 years, respectively.³³³

In a clinic-based cohort of enrollees infected with HIV-1 and HIV-2 in Gambia, fewer individuals with HIV-2 than with HIV-1 developed AIDS (36.4% vs. 27.6%).³³² In this cohort, among those individuals with AIDS, CD4 cell counts were higher in those with HIV-2 in contrast to HIV-1 (176 cells/ μ L vs. 109 cells/ μ L). More individuals with HIV-2 than with HIV-1 had CD4 cell counts greater than 200 cells/ μ L (44% and 33%, respectively). Overall, similar to the French cohort, the most common AIDS-defining conditions included wasting syndrome and pulmonary tuberculosis. The pattern was similar between patients infected with HIV-1 and HIV-2, with two exceptions: compared with those infected with HIV-1, individuals with HIV-2 had significantly more wasting syndrome and significantly less Kaposi sarcoma.³³² After the diagnosis of AIDS, individuals with HIV-2 survived twice as long as those with HIV-1, with median lengths of survival after AIDS diagnosis of 6.3 months and 12.6 months, respectively. Mortality rates were 52/patient years observed (PYO) for HIV-2-infected individuals and 87/PYO for those with HIV-1. At the time of death, CD4 cell counts remained higher for those with HIV-2 than for those with HIV-1 (120 cells/ μ L and 62 cells/ μ L, respectively).³³²

Just as for HIV-1, HIV-2 plasma viral load correlates with progression of disease as measured by CD4 cell decline or mortality. The viral set point is significantly lower in HIV-2 infection than in HIV-1 infection. Recent HIV-2 seroconverters have plasma HIV RNA levels 28 times lower than those of recent HIV-1 seroconverters. For HIV-1, the viral set point has been demonstrated to be a very good predictor of outcome of disease. Differences in viral load throughout most of the natural history of HIV-1 and HIV-2 infection likely account for the differences in progression of disease and transmissibility reported between the two viruses.^{8,15,430,492}

HIV-2 viremia has been associated with more pronounced immunosuppression, more rapid disease progression, and a greater likelihood for death. In a comparison of HIV-1-infected and HIV-2-infected persons with similar CD4 cell counts, the quantitative viral load was significantly lower in those infected with HIV-2.⁴⁸² Plasma viral load is inversely related to CD4 counts, with each decline in CD4⁺ cell count by 100 cells/ μ L associated with an increase in plasma viral load of 0.07 log₁₀ copies/mL.³³³ In this study the risk for disease progression was higher in individuals with plasma viral loads of 1000 copies/mL or greater than in those with plasma viral loads less than 1000 copies/mL—26% versus 6%. In patients with no immunosuppression (CD4⁺ cell count >500/mm³), none of the HIV-2-infected individuals had a detectable plasma viral load, in contrast to 52% of HIV-1-infected persons. Individuals with HIV-2 had a significantly lower mortality rate than that of HIV-1-infected patients or those with HIV-1/HIV-2 dual infections.⁴⁷² Among HIV-infected patients with advanced disease (CD4⁺ counts <200 cells/ μ L), all had a poor prognosis, and no difference in mortality rates occurred among HIV-1, HIV-2, or dually infected patients.⁴⁷² In fact, the mortality rates of HIV-2-infected patients with undetectable plasma viral loads was similar to that of uninfected individuals, whereas HIV-2-infected patients with plasma viral loads of 10,000

copies/mL or greater had mortality rates similar to those observed with HIV-1.⁵⁴⁹

The lower HIV-2 plasma viral load could possibly be due to lower viral replication, enhanced host immune control, or a combination of the two factors. HIV-2 and HIV-1 have comparable cytopathicity. It is clear, however, that the two viruses have different dynamics in vivo, with plasma viral loads set points and plasma RNA levels being approximately 30-fold lower than with HIV-1.^{8,430} At corresponding levels of CD4 cell depletion, despite greatly disparate plasma viral loads, levels of integrated proviral HIV-2 DNA in peripheral blood mononuclear cells are similar to those in comparable groups of HIV-1-infected individuals,^{14,240,430} indicating that HIV-2 is able to establish provirus. HIV-2 viral mRNA accumulates at much lower amount, indicating that HIV-2 has tighter transcriptional control.^{306,490}

Autologous neutralizing antibodies more frequently are found in HIV-2-infected individuals than in HIV-1-infected individuals and also may contribute to the slower disease progression in HIV-2.

Similar to the clinical outcome of HIV-2 infection in adults, slower rates of disease progression and better survival rates have been observed in HIV-2-infected versus HIV-1-infected or dually infected children.^{4,118,386,403,438} In a prospective study in the Gambia, the 18-month mortality rate of children born to HIV-2-infected mothers did not differ significantly from that of children born to HIV-seronegative women (7% vs. 6%, respectively). In contrast, the relative risks for death in children born to HIV-1-infected versus HIV-2-infected or seronegative mothers were increased by 2.3-fold and 2.6-fold, respectively.⁴⁰³

The excess number of deaths in children of HIV-1-infected mothers was caused primarily by HIV-1 infection in the child; the mortality rate was 35% in HIV-1-infected children, as opposed to 9% in uninfected children born to HIV-1-infected mothers. In contrast, no deaths occurred in HIV-2-infected children. In Guinea-Bissau, the overall child mortality rates were similar in children born to HIV-2-seropositive and HIV-seronegative women (16.3% vs. 14.6%, respectively).³⁸⁶ However, despite generally slower progression in HIV-2-infected children, severe immunodeficiency and AIDS occurring early in life rarely have been reported with HIV-2 infection.^{175,353,354} Mortality rates in infants born to HIV-1-infected or dually infected mothers were 2.6 to 4.2 times higher than those in infants born to HIV-2-infected mothers (mortality rates of 133, 82, and 32 per 1000, respectively).¹¹⁷ This finding is similar to that observed in the Gambia, where the childhood mortality rate was 15% for children born to HIV-1-infected mothers compared with 7% for those born to HIV-2-positive mothers and 6% for those born to HIV-seronegative mothers.⁴⁰³ In a small cohort study investigating the survival of children born to HIV-1-positive and HIV-2-positive mothers, the mortality rates for infected children were significantly higher than those for uninfected children.⁴⁷¹

The mortality hazards ratio of HIV-1-infected children was 3.1 times that of HIV-2-infected children but was not statistically significant.

The overall mortality of HIV-uninfected children of HIV-1-seropositive and HIV-2-seropositive mothers was not significantly different from that in children of HIV-uninfected children.⁴⁷³

Treatment

Currently available antiretroviral medications (ARVs) have been specifically developed for treatment of HIV-1, and some ARVs are not active against HIV-2 virus. Combination ART is recommended for the treatment of HIV-2, as it is for HIV-1. Observational cohort studies have shown variable but largely poor outcomes for ART in HIV-2 infection.^{100,140-142,189,333,455} Poorer outcomes of treatment of HIV-2 can be attributed to a number of operational, clinical, and public health challenges, including diagnostic tools that have not adequately differentiated between HIV-1, HIV-2, and HIV-1/HIV-2 dual infections. Failure to diagnose HIV-2 or dual infection may lead to treatment with inappropriate and ineffective ARV regimens, which can result in poor immunologic response and disease progression. Optimal disease monitoring is not possible because there are no commercially available viral load assays to identify virologic failure and no commercially available genotypic assays to identify drug-resistant virus. Lastly, there have been no randomized trials addressing the optimal time to start ART or the choice of first- or second-line therapy for HIV-2. US guidelines

recommend initiating ART before there is clinical progression of the infection or severe immunosuppression.⁴¹⁰

Significant differences exist in the effectiveness of specific ART medications in treatment of HIV types 1 and 2 that must be considered in establishing an effective therapeutic regimen. Nucleoside reverse transcriptase inhibitors (NRTIs) generally show little to no inhibition of HIV-2 in vitro at nontoxic levels.⁵⁷⁹ HIV-2 is intrinsically resistant to NRTIs because of a naturally occurring polymorphism in all HIV-2 isolates.⁵³⁷ NRTIs inhibit HIV-2 but at effective concentrations at least 50 times higher than those that inhibit HIV-1. These concentrations limit the clinical utility of these agents against HIV-2. HIV-2 is also resistant to enfuvirtide, a fusion inhibitor.^{437,578}

HIV-2 is sensitive to currently available nucleoside and NRTI drugs, although with a lower barrier to resistance than HIV-1.⁴⁸⁹

Clinical studies of HIV-2 clones taken from patients receiving NRTI-containing ART confirmed that phenotypic resistance is associated with genotypic changes. Amino acid changes associated with HIV-1 NRTI resistance at M184 and Q151M also seem to occur in HIV-2 and have been associated with NRTI treatment failure.⁵⁴⁷ The significance of other mutations in the HIV-2 reverse transcriptase gene after exposure to NRTI is unknown; also not known is whether mutations in the NRTI gene accumulate in a stepwise fashion, conferring increasing resistance to NRTI therapy.

Protease inhibitors are effective against HIV-2 protease but have variable activity and accelerated genotypic resistance.³⁸⁹ The ritonavir-boosted protease inhibitors darunavir (DRV) and lopinavir (LPV) are more active against HIV-2 than other approved protease inhibitors and are preferred agents for first-line treatment.

The integrase strand transfer inhibitors (INSTs) raltegravir (RAL), dolutegravir (DTG), and elvitegravir (EVG) have demonstrated activity against HIV-2 in vitro. Clinical response to raltegravir was reported in a patient with highly treatment-exposed HIV-2 infection.^{172,585} The CCR5 coreceptor antagonist maraviroc (MVC) appears to be active against some HIV-2 isolates. Use of coreceptor antagonists is hampered by the lack of approved assays to determine HIV-2 coreceptor tropism and by the fact that HIV-2 is able to use a broad range of coreceptors, including CXCR4, CCR5, CCR2, GPR15, and CXCR6.^{170,171,457,585}

Because there are current recommendations for universal treatment of HIV-infected individuals without regard for CD4 count or clinical stage,^{582,583} more HIV-2 infected individuals will be started on ART. Until more definitive data are available, it is recommended that ART-naïve patients with HIV-2 monoinfection or HIV-1/HIV-2 dual infection be started on a regimen containing two NRTIs plus an HIV-2–active boosted protease inhibitor or INSTI before the individual has clinical disease progression.^{410,582,583}

Disease Monitoring

Progression of HIV disease and response to ART are usually assessed by considering clinical, immunologic, and virologic criteria. Clinical assessment and measuring CD4 count are the most readily available means for monitoring disease progression in HIV-2 infection because no HIV-2 viral load assays are yet commercially available. In response to ART, CD4 counts do not increase in HIV-2 infection as dramatically as can be seen in HIV-1 infection,^{22,140-142} further highlighting the need for access to HIV-2 viral loads and genotypic testing as key components of comprehensive care for HIV-2 infections.

192B ■ Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Karin Nielsen-Saines • Mary E. Paul • William T. Shearer

In the absence of treatment, prevalence with human immunodeficiency virus type 1 (HIV-1), a retrovirus, causes a chronic, eventually fatal illness. Human retroviruses include human T-cell lymphotropic viruses (i.e., HTLV-I, HTLV-II, HTLV-III, and HTLV-VI), also known as oncoviruses, and lentiviruses (i.e., HIV-1 and HIV-2). Retroviruses

are RNA viruses capable of transforming themselves into DNA viruses and integrating into the host cell genome. Before 1980, retroviruses were known to cause disease only in animals, but shortly thereafter, HTLV-I and HTLV-II were shown to be associated with human disease.
